The GCI was launched in June 2008 and comprised three main sets of components: a Geo Web Portal (GWP) acting as entry points for the users, a set of registries (components and services, standards and interoperability, and best practice), and a clearinghouse. Data providers were encouraged to register their systems, data resources, and services in the Content and Service Registry (CSR), and the Clearinghouse harvested the metadata from the CSR, acting as a catalog to respond to user requests made through the GWP. During the initial phase of operations, there were three GWPs and three clearinghouses provided on a voluntary basis by organizations in both private and public sectors. In 2010, after a process of testing and review, it was decided to select the GWP operated by the European Space Agency, and the Clearinghouse operated by the US Geological Survey as the bases for the operations of the GCI.

By 2011, it became clear that there was a problem. Only a few hundred datasets and services had been registered by data providers and were available through the GCI, thus making the infrastructure of limited or no value. The approach to developing the GCI was copied from the US federal National Spatial Data Infrastructure, and similar efforts in Canada and Europe (including INSPIRE), which were considered best practice at the time. In fact the NSDI Cookbook (Niebert, 2004) has been for many years the template from which SDIs around the globe were developed. The problem is that this 'traditional' approach to SDI development is founded on the adoption of a limited set of standards that have emerged in the geospatial community (typically those by ISO and OGC), and on having the authority to enforce these standards on the contributing organizations. Already in the case of INSPIRE where the authority exists via the European legal framework, we have tested the limits of this approach when dealing with an infrastructure spanning multiple countries and languages. In the context of GEOSS, that is a global initiative, across many disciplines in the physical, environmental, and social sciences, and built on a voluntary basis (and no additional funding), the approach was faltering. Each discipline had developed over the years its own practices, standards, and protocols, and could see no benefit in making costly changes to adopt the standards requested by the geospatial community. Hence, only a low level of registration and interoperability had been achieved by the GCI by 2011.

A novel approach that was able to make a significant change was the introduction of the Brokering Framework (Nativi and Bigagli, 2009; Nativi et al., 2012, 2013). This framework builds the necessary bridges between different disciplinary infrastructures without asking them to make any changes to their normal way of operating. In more formal terms, brokering introduces a new middleware layer of service offerings in the SDI that realize the necessary mediation, adaptation, distribution, semantic mapping, and even quality checks required to address the complexity of a multidisciplinary infrastructure built by interconnecting disciplinary infrastructures. Brokers can do much more than just facilitate discovery and access of available resources: they may implement new capabilities for users and data providers such as advanced semantic discovery; resource tagging and clustering of results; quality control; data preprocessing and transformation; work flow management; and model interconnection. In essence, there are multiple brokers taking on different functions, but the overall new approach is to concentrate all the mediations in a separate middle layer of the infrastructure without asking each (disciplinary) infrastructure to make changes. The added value of the brokering approach was demonstrated in December 2011 at the plenary meeting of GEO: from a few hundred resources available in the GCI in March 2011, the introduction of brokering made it possible by December to discover some 28 million datasets or services, a two orders of magnitude increase in few months! For this reason, brokering was officially adopted as a central component of GEOSS in 2012 and is now the core of the GCI. Similar complex multidisciplinary infrastructures such as the National Science Foundation EarthCube (http://earthcube.ning.com/) are also considering the brokering approach (Nativi et al., 2011).

From Multidisciplinary to Participatory Science

As noted at the beginning of Section Multidisciplinary Interoperability, ICSU recognized the crucial importance of engaging more closely the users of scientific research, citizens, and decision makers, not just by communicating science more effectively but by fostering the active involvement of users in the scientific process itself. This form of participatory science is all the more necessary as the explosion of social media exposes scientists more than ever before to claims and counterclaims, and raises the need for transparency and openness of both data and processes on which scientific discoveries are made. This is the sense of the new Open Data initiatives in Europe and globally (see for example the Research Data Alliance http://rd-alliance.org). Social media provides also many new opportunities for participatory science, with citizens acting as producers and not just consumers of information.

There is long tradition of calling on volunteers to provide information relevant to science, as for example the Bird Count in the USA (http://www.birdsource.org/gbbc/) and Spring Watch in the UK (http://www.bbc.co.uk/nature/uk/). What has made a significant difference recently is the diffusion of the Internet-based and social networks that have exponentially increased the amount of geographically located information produced by individuals. In August 2006, geotagging facilities at Flickr started to operate; and by the year of 2007, more than 20 million geotagged photos had been uploaded to Flickr. In August 2011, Flickr announced its 6 billionth photo, with an increasing 20% year-over-year, over the last 5 years (http://blog.flickr.net/en/2011/08/04/6000000000/). Similarly, Twitter was born in 2006. The most impressive information is the increasing rate of messages. In 2010, the average number of Tweets sent per day was 50 million (http://blog.

twitter.com/2011/03/numbers.html), while in March 2012 it was 340 million (http://blog.twitter.com/2012/03/twitter-turns-six.html). Also in 2010, the geotagging feature of the Tweets was added. Although the amount of geo-enabled messages is around 1% of all messages, this still means 1 million geotagged information messages per day. The universe of Volunteered Geographic Information (VGI) (Goodchild, 2007), or neo-geography, is not uniform and Coleman et al. (2009) provide a useful categorization of contributors of VGI, while Craglia et al. (2012a) report on a large-scale experiment to assess the quality of VGI and its added value compared to official information in the case of forest fires.

The integration of SDIs, which are traditionally based on authoritative information from public administrations, with information from citizens and new networks of sensors promises a real step change: form static to dynamic information flows about the Earth, from a few users in the scientific or policy-making community to a participatory framework for all. Digital Earth is the term that encompasses this vision of a dynamic and participatory framework, the next frontier of SDIs (Goodchild et al., 2012; Craglia et al., 2012b). The next editions of this Encyclopedia will document how far promise has matched reality in implementing this vision.

Abstract

Spatial decision support systems (SDSS) combine storage, search, and retrieval capabilities of geographic information systems with decision models and optimizing algorithms to support decision making concerning spatial problems. These systems allow decision makers to use multiple spatial criteria to make locational choices by exploring alternatives, given spatial and attribute information. Characteristics of SDSS are becoming incorporated in social science theories and models that explain spatial decisions.

Introduction

Spatial decision support systems (SDSS) are computer-based systems that combine storage, search, and retrieval capabilities of geographic information systems (GISs) with decision models and optimizing algorithms to support decision making concerning spatial problems. Applications include political redistricting, route selection, facility location, and land use planning. SDSS are used increasingly in both private and public sectors. These systems allow decision makers to use multiple spatial criteria to make locational choices by exploring alternatives, given spatial and attribute information. In some SDSS, the users generate alternatives interactively. The capabilities of the SDSS manipulate the geographic information, report the characteristic attributes for each alternative, and allow users to participate in the choice evaluation process. Research in SDSS entails capturing and incorporating the knowledge of experts.

People frequently make choices that involve evaluating geographic context. Decision makers apply multiple spatial criteria to complex geographic data, such as information that relate to selecting routes, making service areas, or defining environmental hazardous areas. In social science, such complex decision-making problems are often ill-structured, in which case a set of theories, methods, and techniques must be developed. It has become common to link these together in computer software that operates on spatial data.

A number of challenges may occur when making decisions for ill-structured problems. First, it may be unclear how much of the attainment of one spatial criterion should be sacrificed in order to attain a given amount of another. The decision maker often wants to explore alternative solutions and reach a decision about a desirable solution after extensive exploration of the spatial context and the attribute information. That is, decision makers' preferences for a particular solution may be influenced by what can be attained in a particular context. Decision makers may have preferences for abstract entities, and the implementation of these preferences is mediated by knowing what can be attained. SSDS are designed to facilitate the exploration of these spaces, and thus to assist the search for acceptable solutions. A second challenge is the imperfection of spatial databases with respect to missing variables and erroneous data. Decision makers will sometimes consider their personal knowledge or search for additional facts before making a decision. A third challenge is that decision makers may choose not to accept a model's results due to concerns regarding the results' validity. All three challenges can lead decision makers to ask for computer-based, interactive, support systems that explore the problem and search for various solutions.

Solutions to SDSS problems normally have both spatial and nonspatial characteristics. Spatial characteristics concern the shapes of features and the distances among the features. Nonspatial characteristics are the attributes of those features, such as can be recorded in a table. Solutions to all SDSS problems exist in geographic space as well as in attribute information. As the geographic space of the solution to any problem changes, its attribute information changes too. For example, in making districts from which voters will elect representatives, the geographic solution space includes the map of the boundaries of the districts, the shapes of the districts, and the connectivity of census tracts that belong to the same district (Ricca and Simeone, 2008). The corresponding attribute information describes numbers of eligible voters in each district, voters' party affiliations, voters' past behaviors, and any attribute for which data are available and that a politician may view as relating to voters' likely future voting behavior. Such attributes might be voters' ethnicity, income, age, religion, etc. Any participant in a redistricting exercise may want to see how any change in the boundaries is accompanied by changes in any or all of these attributes. The redistricting process is to find solutions using multiple criteria concerning geographic space and attribute information. For example, typical spatial criteria for political redistricting are each district should be contiguous, districts should follow natural boundaries like bodies of water, districts should respect the integrity of communities, and districts should be compact to prevent the formation of odd-shaped districts that raise the suspicions of gerrymandering (Bozkaya et al., 2003). The nonspatial attribute information of the districts include criteria such as each district should have an approximately equal number of people, each district should have socioeconomic homogeneity to ensure representation of residents who share concerns, the collection of districts should allow representation of important minority groups, etc. Redistricting uses quantifiable criteria to compare one solution with another to find the better ones, and to exclude solutions that do not satisfy the criteria. A system for

simultaneously computing various regionalizations of territory constitutes an SDSS for electoral redistricting.

Components of SDSS

Figure 1 shows the components of a common SDSS as well as the flow of the decision-making process using SDSS. Besides the user interface and report generator, the SDSS consist mainly of three subsystems: a GIS, a model management system, and a group decision support system. After users define their spatial decision task, they interact with the three subsystems through the user interface of SDSS. GIS helps to visualize the data, analyze the data using spatial analysis tools, create supportive data layers, and store the data using the database management system. The graphical interface of SDSS also allows users to formalize their problems so that users can understand or construct their models using components that the model management system has. The model management system is then able to use the data managed by GIS in order to find a solution using existing algorithms. The group decision support subsystem provides cooperative work computing environments that can enhance SDSS by enabling group members to observe, manipulate, and evaluate solutions collectively, thus providing mechanisms for conflict resolutions. Finally, the SDSS generate reports so users can evaluate all the alternatives. Users may adopt the solution or go back to redefine the problem and redo the entire process to find a better solution.

Role of GIS

Various types of SDSS can be defined according to how geographic space and attribute information are generated. SDSS consist of tools for manipulating geographic information and reporting the attributes of the outcomes. The simplest SDSS incorporate the capacity to convey information from the geographic space to the attribute information or from the attribute information to the geographic space. These are key capabilities of a GIS.

A GIS is a system of hardware, software, and procedures that can support geographical decision making through the acquisition, management, manipulation, analysis, and display of spatially referenced information (Church and Murray, 2009). GIS provides decision makers the ability to visualize and analyze the input data as well as to model results from the decision-making process (Murray, 2010). Over the last several decades,

Figure 1 Flows among components of a spatial decision support System.

the fast growth of technologies for collecting spatial data, computing larger data sets, and using the Internet has aided the diffusion of GIS technology to a greater number of organizations. GIS is powerful because it has the ability to handle spatially explicit data as well as nonspatial data. Both types of data are managed using Relational Database Management Systems. GIS can be used for producing maps and integrating multisource data sets, such as data concerning population, topography, hydrology, climate, vegetation, transportation, etc.

In order to represent the real world in a digital environment, GIS uses two types of data: raster and vector. Raster data consist of pixels arranged on a rectangular grid, where each pixel in the grid has an individual value for each characteristic being represented. One type of spatial data manipulation for a GIS-based SDSS on raster data is map algebra. Map algebra involves the operations of addition, subtraction, multiplication, division, and other mathematical functions acting on individual pixels. Vector data consist of points, lines, and polygons. For vector data, the manipulation normally involves transforming and combining the basic geographic features. Spatial queries can also be conducted by defining the spatial characteristics such as within, outside, and intersect. Spatial queries extend traditional SQL functionalities to include geometric operations. For both raster and vector data, distance related operations such as buffer and proximity are very useful and widely used in some SDSS applications to create derived data layers with attributes in desired ranges. Longley et al. (2011) offer further elaboration and discussion of GIS.

The term SDSS is often reserved for systems that combine the functions of GIS with multicriteria decision analysis (MCDA) and optimizing models. These are developed for contexts that involve manipulating of information, generating of preferences, modeling of choices, and searching for locations that meet users' needs.

Two popular GIS-based SDSS softwares are Idrisi and ArcGIS. Idrisi is a commercial GIS software based mostly on raster data. Idrisi contains over 300 modules for analysis and display of spatial information. Idrisi has decision support modules including weighted linear combination (WLC), analytical hierarchy process (AHP), ordered weighted averaging (OWA), and multiobjective land allocation (MOLA), among others. Idrisi also has a wizard to assist in selection of appropriate decision techniques and a graphic modeling environment called Macro Modeler to design sequences of operations (Eastman, 2012). ESRI's ArcGIS suite of products provides the building blocks needed to implement WLC, including weighted overlay and map algebra, as well as a graphical modeling environment called Model Builder in which users can build customized SDSS.

Multicriteria Decision Analysis

Spatial decision problems typically involve a large set of possible alternatives, especially when there are multiple evaluation criteria. The alternatives are often evaluated by several people including decision makers, managers, stakeholders, and interest groups. MCDA analyzes potential actions based on multiple criteria, using decision rules to aggregate those criteria in order to rate or rank the alternatives (Eastman, 2012). Malczewski (2006) conducted a survey of literature on GIS-based MCDA. He remarks that criterion is a generic term that includes attributes and objectives, while MCDA is a blanket term that includes multiattribute and multiobjective decision making. During multiattribute decision making, users of SDSS apply various sets of weights and various methods to aggregate criteria in order to participate directly in the choice evaluation process. Widely used aggregation and weighting methods include Boolean overlay, WLC, AHP, OWA, which are described below:

1. Boolean Overlay is a method to create a new map by overlaying existing maps while using the Boolean logic functions, i.e., AND, OR, NOT. This process is easily understandable and useful for initial analysis. For example, suppose a local authority is trying to start new residential development, and the land they are looking for must be less than 30 miles from a highway, on flat slopes, and in residential zoning. Maps of parcels that satisfy each criterion could be created and then Boolean overlay could find parcels that meet all criteria.
2. WLC is a method of map overlay that aims to capture some of the value judgments and expert opinions within the spatial analysis procedure (Malczewski, 1999). Also known as simple additive weighting, WLC multiplies standardized criterion scores by relative criterion weights for each alternative. The steps are (1) define each criterion in terms of a map layer, (2) standardize each criterion map layer, (3) define a weight for each criterion, (4) construct the weighted standardized map layers, (5) generate an overall score by adding the weighted standardized map layers, and (6) rank the alternatives according to the overall performance score.
3. AHP is a priority-ranking technique that helps to break down complex problems into elements. AHP arranges the elements into a hierarchy using subjective judgments in order to assign numerical values based on the relative importance of these elements to the overall goals (Saaty, 1980). AHP generates weights for each criterion, which can then be used in a WLC process.
4. OWA extends WLC by using criteria-order weights to control the levels of criteria trade-off, allowing decision makers to place themselves along a continuous spectrum of risk tolerance (Yager, 1988). Based on fuzzy methods, OWA provides a consistent theoretical link between Boolean overlay and WLC, and thus opens the possibilities for aggregation of criteria (Jiang and Eastman, 2000).

Multiobjective decision making includes two types of methods: mathematical programing and heuristic methods. Objective and constraint are two terms that are commonly used in multiobjective decision making. An objective is a goal that guides the structuring of decision rules. A constraint serves to limit the alternatives under consideration. Mathematical programing methods formulate the objectives and constraints into a set of equations and inequalities concerning decision variables, and then solve them simultaneously. Mathematical programing methods consider all possibilities in the solution space and thus ensure an optimal solution. However, solving mathematical programing models can sometimes be computationally intensive and thus very time consuming. As an alternative to mathematical programing, heuristic methods

explore the solution space by identifying feasible solutions from which an acceptable one can be found (Tong and Murray, 2012). Although heuristic methods lack the capacity to ensure global optimality, heuristic methods are designed to generate acceptable solutions in a reasonable time frame. There exist some generic heuristic methods such as simulated annealing and evolution algorithms.

Simulated annealing randomly searches for solutions within the solution space. Initially, simulated annealing accepts worse solutions with a high probability value in order to avoid local optima. This probability is then gradually decreased to enhance the selectivity of the method toward improved global solutions, which is a process analogous to the cooling procedure for the control of crystallization during annealing in metallurgy (Kirkpatrick et al., 1983).

Evolution Algorithms follow the logic of how nature improves the survivability of a species through natural selection, reproduction over generations, and random genetic changes called mutation and crossover (Michalewicz and Fogel, 2004). A genetic algorithm (GA) is one type of evolution algorithm. In a GA, individual solutions to a problem are represented in an appropriate discrete structure, e.g., a sequence of bits that can be set according to the presence or absence of a specific characteristic. The possible solutions are initialized and each solution is assigned a fitness value, which is usually derived from an objective function. A GA is then executed iteratively where each iteration creates a new generation of solutions. In each generation, solutions with the highest fitness values have greater probabilities of being selected and reproduced to form a new generation. Evolutionary operations, e.g., mutation and crossover, are applied in each iteration so that the overall fitness of the population can be improved as the generations progress (Stewart et al., 2004).

MOLA is a heuristic method to solve land allocation problems (Eastman, 2012). MOLA determines a compromise solution that attempts to maximize the suitability of the overall solution given: a suitability map for each land use, a relative weight for each land use, and the amount of area to be assigned to each land use. MOLA usually allocates each pixel to the land use with the closest ideal point, but alternatively MOLA can allocate the pixel to an alternative land use that has a higher weight than the land use with the closest ideal point.

Greene et al. (2011) provide a summary of MCDA methods and a decision tree to aid the selection of appropriate methods. As an example, Ratick and Osleeb (2011) evaluated multiple MCDA methods to construct composite indices to measure the vulnerability of populations susceptible to lead contamination in the Dominican Republic.

Location Optimizing Algorithms

Many decision makers want to select locations to optimize some defined outcome. A large literature describes models for finding optimal locations, routes, etc.

Ratick et al. (2008) discussed an application of location models for locating storage facilities to supplement existing facilities in order to respond to the potential effects of natural and anthropogenic hazards. They used location modeling to determine the number of facilities and where to locate the facilities. The concept of backup facilities was considered to explore the interrelationships among hazards, vulnerability, and location.

Murray and Tong (2009) demonstrated an example where GIS-based SDSS are used in siting fire stations through human–computer interactions. Facilities were placed and relocated by users, while GIS was used for evaluating placement configurations.

Williams (2002) and Shirabe (2005) developed algorithms to search for the location of one site that is either most suitable for a certain land use or has the least cost to acquire. Both of their articles aimed to achieve contiguity of the site, meaning all the pixels contained by the site are connected. They both formed mathematical programing models but used different constraint sets to force the solution to be contiguous.

Williams et al. (2005) give a synthetic review of models and the spatial attributes considered for the optimal selection of nature reserve sites to protect a diversity of species or other conservation features. Spatial attributes such as the reserve shape and connectivity affect the persistence of species, the general ecological functioning of the landscape, and the ability to manage the reserve.

The traveling salesman problem is a route selection problem that asks the question: given a list of cities and the distances between each pair of cities, what is the shortest route that visits each city once and returns to the original city? It has applications in planning, logistics, as well as the manufacture of microchips. Both mathematical programing and heuristic algorithms have been developed to solve this problem efficiently (Applegate et al., 2011).

Network location problems occur when new facilities must be allocated on a network, e.g., a transportation network. These problems exist in the private sector, such as when a retail company would like to locate storage facilities. These problems exist also in the public sector, such as when a municipality would like to locate fire stations. Researchers have categorized some classic location problems in families such as the set covering problem, the *p*-center problem, and the *p*-median problem (Daskin, 2011). One example of a set covering problem is to minimize the number of fire stations so that all demand nodes are within a given response time, which is the time for a fire truck to travel to a demand site from the nearest fire station (Toregas et al., 1971). The *p*-center problem is to allocate a fixed number of fire stations on a network in order to minimize the maximum response time to any demand node (Tansel et al., 1983). If we use a storage facility as the example, then the *p*-median problem is to allocate a fixed number of facilities to serve demand nodes so that the transportation cost is minimized (Hakimi, 1964). The transportation cost considers the amount of product needed at each demand node and the distance between the demand node and the facility that serves the demand node. Those problems are well studied and there exists both mathematical programing and heuristic algorithms for the solutions.

Group Decision Support Systems

Spatial decisions are often made by collaborative efforts involving groups of people. Nyerges and Jankowski (1997)

discuss adaptive structuration theory in a GIS environment to assist groups who are involved in public land planning controversies, such as hazardous waste cleanup and habitat redevelopment.

Some SDSS incorporate methods for reconciling various views. Couclelis and Monmonier (1995) discuss this application and offer a computer-supported system to help promote the resolution of planning controversies. Their system uses GIS capabilities to present spatial details of the planning situation and uses a graphic interface to encourage reconciliation of opposing views. Armstrong (1993) describes how cooperative work computing environments can enhance SDSS by enabling group members to observe, manipulate, and evaluate alternative plans collectively, then to provide mechanisms for conflict resolution.

Research in SDSS seeks to capture and incorporate knowledge of experts (Armstrong et al., 1990; Leung et al., 1997). Some of the knowledge concerns the algorithms and their links to the decision task. Other knowledge is substantive knowledge about the processes that must be modeled.

Implementations of SDSS

The academic literature has many examples of prototype implementations of SDSS. Commercial SDSS applications include generic SDSS and domain-specific SDSS. Sugumaran and Degroote (2010) listed existing tools and softwares that fall into these two categories.

Generic SDSS allow users to address a wide range of problems. SDSS normally provide a rich set of decision support components such as spatial database management, analytical models, and a framework to allow rapid assembly for a specific application. Examples include systems such as Idrisi's Macro Modeller, ArcGIS's Model Builder, and Erdas' Imagine. These systems provide a graphical user interface that allows construction of models without any software development. Decision flows are represented by a graph, where modules and data are stored as nodes of the graph, while the connections between the nodes are stored as vertices. Graphical modeling tools give a clear layout of the decision process. Some tools provide additional control over the flow of the execution of components in the model, while other tools allow for the creation of iterative processes, so that batch processing of a large data set is possible.

Domain-specific SDSS are developed to support decision making for specific problems that are complex, yet occur with sufficient frequency to support the overhead cost of developing and testing. For example, Marxan is a freely available system developed for conservation planning. It is designed to solve reserve design problems by achieving a desired representation of biodiversity features for the least cost (Game and Grantham, 2008). Marxan uses simulated annealing to find near-optimal solutions. INDEX is a suite of planning tools that can be used for assessing community conditions, designing future scenarios, measuring a scenario's success, etc. INDEX also allows comparison of plan goals versus development proposals. CommunityViz is another widely used planning SDSS tool similar to INDEX. It is an extension to ArcGIS software and includes a large suite of visualization, analytical, and communication tools. Visualization capacities are emphasized in this tool that allows users to experiment with various scenarios and view results in a variety of formats including charts, tables, reports, maps, and three-dimensional models.

Looking Forward

SDSS represent the integration of ideas, methods, and techniques from many social, behavioral, and management sciences. The usefulness of SDSS in the policy and planning sciences is based on the degree to which SDSS successfully incorporate the findings and approaches of these sciences. SDSS have an important link with the fast growing field of geographic information science. The rapid development of national spatial data infrastructures provides a rich and expanding database that SDSS can use.

Challenges still remain for SDSS to address complex multidisciplinary issues that have spatial dimensions. Technological challenges concern the selection of software platforms, the development of user-friendly interfaces, the integration of spatial models, etc. Social, organizational, educational, and policy challenges must also be overcome (Sugumaran and Degroote, 2010). For example, the interaction with users during every stage of the development process is crucial for the success of SDSS, thus SDSS require support from all management levels in order to be incorporated into important decisions. Many individuals from disciplines that might benefit from the use of SDSS are unaware of the potential benefits. Spatial decision-making processes and tools, such as SDSS, must be included in university curricula. SDSS have become a science that builds upon the successful development of models concerning behavioral, social, and political processes. Theories and models of these processes must contribute to SDSS as the applications of SDSS expand. SDSS have become an important element in social science theories and models to explain decisions. The evolution from the use of social and behavioral models as exogenous units into SDSS to the models' incorporation as endogenous units into SDSS is an important development in the social sciences. This development marks the more explicit incorporation of geographic variables in social science theory and method.

Spatial Dynamics and Crime

Martin A Andresen, Simon Fraser University, Burnaby, BC, Canada

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Crime and its spatial dynamics have a long history dating back to the early 1800s in France. In this article, I review four subfields of research within spatial criminology that explicitly consider crime and its spatial dynamics: spatially referenced crime rates, location quotients, geographic profiling, and crime and place. The latest research from these subfields are reviewed with some discussion of their future directions in understanding spatial dynamics and crime.

Introduction

Crime and its spatial dynamics have been studied for close to 200 years since the work of André-Michel Guerry (1833) and Adolphe Quetelet (1842), French and Belgian, respectively. Their work was not only important for spatial criminology, but positivist criminology, more generally. Since this time, a large body of research has emerged that investigates the spatial dynamics of crime at a variety of scales and contexts.

There are many dimensions of spatial criminology that are of particular interest at this time, including: understanding the role of police foot patrol and car patrol in reducing crime, understanding the crime drop of the 1990s, furthering the understanding of relationships, such as unemployment and crime, and helping to understand the transition economies in central and eastern Europe. However, in this article, I will discuss four areas of research in spatial criminology that are explicitly concerned with the spatial dynamics of crime: spatially referenced crime rates, the location quotient, geographic profiling, and crime and place. Though these may not be the only aspects of spatial criminology that are explicitly concerned with the spatial dynamics of crime, they have all received a lot of interest within the field and continue to offer fruitful avenues of research in the future.

Spatially Referenced Crime Rates

In order to calculate a crime rate, there are two pieces of data that are necessary: crime data and population at risk data, shown in eqn [1]. The crime count is literally the count of criminal events in some defined geographic area. This count is most often based on official crime data, emerging from some aspect of the criminal justice system. The most well-known official crime data are the Uniform Crime Reporting (UCR) data. These data had its beginning in the United States in 1930 and now nearly all law enforcement agencies in the United States provide data to the Federal Bureau of Investigation for the UCR counts (Mosher et al., 2011; FBI, 2012). In Canada, the UCR began later, in 1962, and is gathered by the Canadian Centre for Justice Statistics – responding to the UCR survey in Canada is mandatory. In 1988, a new version of the UCR in Canada was started that added information regarding incidents, victims, and accused persons. This new UCR is referred to as UCR2; equivalent data in the United States are collected under the National Incident-Based Reporting System, that began in 1987 (FBI, 2012; Statistics Canada, 2012). Another form of official crime data is calls for service data from the police. Though often considered unofficial because these data are not dependent upon a criminal charge and often represent police activity, these are very useful data because a geographic location and time is most often included and the calls for service can be separated to only include the calls that the police identify as a criminal event (Sherman et al., 1989).

$$\left(\frac{\text{Crime count}}{\text{Population at risk}}\right) \times \text{Scalar} \qquad [1]$$

Despite the widespread availability of these official crime data, there are a number of limitations. First, crime reporting can vary from police detachment to police detachment. This may be due to factors such as the local policing and/or population culture considering factors such as (a lack of) tolerance on particular issues. Second, not all criminal events are reported to the police. In Canada, only 31% of criminal victimization was reported to the police in 2009, down from 34% in 2004 and 37% in 1999 (Perreault and Brennan, 2010). This is of critical importance in spatial criminology because if the spatial patterns of crime for official data are different from the spatial patterns of crime more generally, all inference from official data may be spurious. However, very little can be done regarding these first two limitations.

A third limitation is in regard to the need for population at risk data to calculate the crime rates. In spatial criminology, that often uses the census tract as its spatial unit of analysis, the most common source of population at risk data is the census – resident population. These data are very easy to obtain and high quality, but there are two issues with using these data. First, censuses are only undertaken every 5 (Canada) or 10 years (United States and United Kingdom) in most countries. Consequently, depending on the date of the crime data obtained there may be as many as 9 years discrepancy between crime count and population at risk data. If populations are stable over long periods of time this is not problematic, per se, but in cities that grow this could lead to significant overestimates of crime rates if crime counts are for a later year than the resident population.

The second issue with using the resident population from a census as the population is risk is whether or not it is an accurate representation of where people are. This is a critical question in spatial criminology because if the crime rate is to represent an overall measure of risk (Boggs, 1965) the variable representing the population at risk should measure where

 http://dx.doi.org/10.1016/B978-0-08-097086-8.45087-7

people actually are. Recent research on this issue has shown that the ambient population can be quite different from the resident population leading to changes in inference regarding spatially referenced crime rates (Andresen, 2006, 2013; Andresen and Jenion, 2010). In this work, data from the Oak Ridge National Laboratory was used to measure the ambient population that was defined as the number of people in a square kilometer averaged over a 24-h period for any typical day of the year – see Andresen (2006) for details of these data.

In an investigation of the similarity between maps of resident-based and ambient-based crime rates, Andresen and Jenion (2010) found that, despite the visual appearance of similar spatial patterns and a statistically significant relationship, resident-based crime rates were very poor predictors of ambient-based crime rates. Though we do not discuss this prediction, this is what we assume when we use the resident population: it may not be the best measure, but it is representative of the true population at risk. Moreover, places that attract populations throughout the day, measured using the ambient–resident population ratio, are commercial/shopping areas and major transportation routes.

In subsequent research, Andresen (2011, 2013) showed that ambient-based crime rates exhibited significant differences to resident-based crime rates in the context of local analysis, local Moran's *I*. In this work, not only did the spatial pattern of clustering change with some units of analysis changing statistical significance, but also when statistically significant in both analyses the classifications in some places would be completely different – most often, high crime areas remained high crime areas and low crime areas remained low crime areas, but the units of analysis contained within each of those classifications changed. In a spatial regression context, the similarity of results for resident- and ambient-based crime rates differed on the year of data and the size of the unit of analysis. In some cases, the results from the ambient-based crime rates outperformed the resident-based crime rate results in the context of: greater (pseudo) R^2 values, more reasonable parameter estimates, more statistically significant relationships, and a better concordance with theoretical expectations. In other cases, there were very few differences with limited consequences to the results.

Overall, this research shows that there are good theoretical reasons to question the use of the commonly used resident population in spatially referenced crime rates – crime rate calculations for what may be considered a 'closed system' of population movement such as a metropolitan area or a subnational unit (province or state) will most probably be unaffected. Though there may not necessarily be an impact on the results, such an impact is definitely possible and may alter any interpretations. Moreover, just because there is no impact for 1 year of data and 1 spatial unit of analysis, an impact may be present for a different year of data and/or a different spatial unit of analysis even in the same city.

A Spatial Alternative Measure of Crime: Location Quotient

As should be clear from the preceding section, the calculation of crime rates has two sources of measurement issues: the criminal event counts and the population at risk. There is an alternative to the crime rate that only relies upon criminal event data, however, that has been used in spatial criminology for 20 years but is arguably underutilized – the location quotient. The location quotient is a specifically geographic statistic that measures the over- or underrepresentation of some activity in a spatial unit of analysis relative to the entire study area. The location quotient is calculated as follows:

$$\mathrm{LQ}_{\mathrm{in}} = \frac{C_{\mathrm{in}}/C_{\mathrm{tn}}}{\sum_{n=1}^{N} C_{\mathrm{in}} \Big/ \sum_{n=1}^{N} C_{\mathrm{tn}}} \qquad [2]$$

where C_{in} is the count of crime i in subregion n, C_{tn} is the count of all crimes in subregion n, and N is the total number of subregions. The location quotient is a ratio of the percentage of a crime type in a subregion relative to the percentage of that crime type in the region as a whole; neighborhoods within a city, for example. If the location quotient is equal to one, the subregion has a proportional share of a particular crime; if the location quotient is greater than one, the subregion has a disproportionately larger share of a particular crime; and if the location quotient is less than one, the subregion has a disproportionately smaller share of a particular crime. For example, if a subregion has a location quotient of 1.20, that subregion has 20% more of that crime than expected given the percentage of that crime in the region as a whole. Consequently, it can be said that this subregion 'specializes' in that particular crime type.

First introduced to the criminological literature by Brantingham and Brantingham (1993) as a descriptive tool, the location quotient has been used by subsequent researchers to investigate a number of phenomena, such as drug markets, theory testing, shootings, and automotive theft markets – see Andresen (2013) for a review. The utility of the location quotient is that by using an alternative measure of criminal activity we are able to identify different patterns. For example, as outlined in Andresen (2013), the spatial patterns of crime rates versus location quotients are somewhat similar for a number of crime types, but notable differences emerge when considering specialization versus risk. In the case of assault in Vancouver, Canada, a crime rate map indicates that this crime type is highly concentrated in Skid Row. However, the east side of the city (and the north east side in particular) exhibits a lot of assault specialization. What does this mean? In order to answer this question, both the crime rate and the location quotient need to be considered. First, the risk of an assault is greatest in Vancouver's Skid Row. But, given that an individual is going to be a victim of crime, it is more likely to be an assault on the east side of the city relative to the west side of the city. Similar differences in the spatial patterns of crime emerge for other crime types as well, but not always in the same places: robbery, sexual assault, theft (more specialization of this crime type is present on the western more affluent side of the city), theft from vehicle, and theft of vehicle.

Perhaps the most interesting application of the location quotient in Andresen (2013) is burglary. The burglary crime rate map indicates that burglary has its greatest risk in and around the central business district and skid row – standard

social disorganization theory predictions. However, the location quotient map shows that the burglary specializes the most on the relatively affluent west side of the city where the burglary rates are the lowest. Of course, this does not mean that burglary is more frequent on the west side of the city than the crime rate map indicates, but it does mean that if an individual is going to be a victim of a crime on the west side of Vancouver it is most likely going to be a burglary. Though no research has been undertaken to support this claim, it has been hypothesized that this may explain some aspects of the fear of crime in low crime neighborhoods: though the burglary rate may be low, everyone whom an individual speaks to about criminal victimization has referred to a burglary of their home so other residents in the neighborhood begin to fear that crime.

Another interesting application of the location quotient was an attempt to understand the increasing crime rate from east to west in Canada that has been present, but not well understood, for at least 50 years (Andresen, 2009). For decades, the western provinces have had greater than national average crime rates across most crime types. However, no such pattern emerged for the location quotient. In the cases of violent crime, there were location quotients with moderate overrepresentation, but for provinces in western, central, and eastern Canada; in the case of property crime, no province had notable overrepresentation. In fact, the territories that are historically characterized by the greatest violent and property crime rates had the lowest location quotients for property crime – all three territories were overrepresented for violent crime, however. What this means is that the risk of criminal victimization is greatest in the west, but given that an individual is going to be a victim of crime, there is no spatial pattern that emerges to state that individual will be the victim of a particular crime type. In other words, the western provinces are not disproportionately violent than other areas in Canada; they simply have more of everything.

Lastly, Andresen (2013) also presented an inferential application of the location quotient (spatial regression) that produced some interesting results. Most important, the workhorse theories used in spatial criminology (social disorganization theory and routine activity theory) performed well in the context of crime specialization. However, because the dependent variable measured specialization not risk, the interpretations of the estimated parameters are different. In some circumstances these differences are subtle such that the estimated parameters have the same sign, but how one interprets the results changes; in other contexts, the sign is opposite from the expectation in a crime rate context (a negative relationship between burglary and the unemployment rate, for example) that requires a completely different, but theoretically justified, explanation.

In all of the applications of the location quotient, the researcher is forced to ask different questions with regard to the spatial pattern of crime, sometimes subtle and sometimes not. Asking these different questions, it is argued, allows the researcher to obtain a better understanding of the phenomena of crime. As such, the use of alternative measures of crime, particularly in a spatial context, should not be used to replace crime rates, but to supplement crime rates for a deeper understanding of the spatial dynamics of crime.

Geographic Profiling

One of the more well-known applications of the theories within spatial/environmental criminology is geographic profiling. Developed by D. Kim Rossmo, geographic profiling may be thought of as understanding the spatial dynamics of serial crime. Geographic profiling is an investigative methodology that uses the locations of a connected series of criminal events to determine the most probable area of the offender's residence – technically geographic profiling is used to identify the anchor point from which a serial offender bases his or her movements, but this is most often the residence. Because geographic profiling uses a connected series of criminal events, the most common uses of geographic profiling are serial murder, rape, arson, and robbery. However, geographic profiling may also be used for nonserial crimes that involve multiple locations. The major function of geographic profiling is to prioritize a list of potential offenders to aid in a corresponding investigation. Geographic profiling has proven to and continues to be a useful tool for the practice of investigative policing as well as the understanding of serial offenders from an academic perspective. Some of the more interesting recent geographic profiling applications have included: cellular telephone switch tower sites in kidnapping cases, the stores in which bomb components have been purchased, and a historical analysis of the locations of anti-Nazi propaganda postcards in left in the streets of Berlin, Germany, in the early 1940s (Rossmo, 2014). Additionally, there have been new applications of geographic profiling that have proven to be very instructive, but for different reasons: terrorism and biology/zoology and epidemiology (Rossmo, 2012).

As stated above, standard geographic profiling uses the related locations in a series of criminal events to help identify the offender's residence. At this time, geographic profiling has been applied to help military analysts identify the location of enemy military bases (Brown et al., 2005), but it can also be used to identify the targets of terrorist attacks. The study of terrorist activities has identified the existence of 'terrorist cell sites.' These terrorist cell sites may be meeting places, rented apartments, etc. that are used as part of the planning of a terrorist attack. As it turns out, there is a strong spatial component to these terrorist cell sites. The research undertaken by Rossmo and Harries (2011) goes through how geographic profiling may be used to identify terrorist targets using these terrorist cell sites. Effectively, this use of geographic profiling is undertaken by taking the method of geographic profiling and turning it on its head. Rather than attempting to help identify the offender, geographic profiling is used to help identify the victim, whether that victim is a place or a person. As it turns out, terrorist cell sites are set up along the same principles as other offending activities. A nonterrorist offender tends to search for criminal targets in known areas, close to home but not so close as to reveal his or her identify. A set of terrorist cell sites tend to be organized close to but not too close to the target of the attack. Consequently, if the terrorist cell sites are considered the 'connected series of criminal events' the geographic profile can then be interpreted as helping to identify the target of the terrorist attack rather than the home of the offender. This new application of geographic profiling has

obvious benefits to counterinsurgency and counterterrorism operations as another tool for identifying potential targets of terrorist attacks based on known terrorist cell site activities as well as the most probable locations of enemy military bases. This shows the reach and power of how the understanding of the spatial dynamics of crime may be useful in other domains of research and practice.

One of the other new applications of geographic profiling is in the realm of biology and zoology. In an analysis of two species of bats in Scotland, Le Comber et al. (2006) were able to show the utility of geographic profiling in analyzing the foraging patterns of the different species. Specifically, the authors were able to show that based on the use of geographic profiling the two different species of bats exhibited different patterns of foraging. Raine et al. (2009) were able to show that geographic profiling could be used to identify the likely locations for the nests of bumblebees, including the consideration of flower (target) densities. And Martin et al. (2009) were able to use geographic profiling in order to discover that the spatial patterns of shark predation were not random. The authors were able to identify the search base (anchor point) for these sharks in South Africa and understand the predatory strategies of these sharks considering factors, such as prey detection, capture rates, and competition from other sharks. Perhaps most interesting, Raine et al. (2009) found that smaller (younger) sharks exhibited significantly greater areas for their prey search patterns than larger (older) sharks. This suggests that as sharks age they learn, or at least refine, their hunting strategies. And lastly, geographic profiling has been applied to epidemiological research to identify the origins of infectious diseases, such as contaminated water sources for cholera and mosquito breeding grounds for malaria (Le Comber et al., 2011), and identifying the source locations for invasive species (Stevenson et al., 2012), both using the current locations of these phenomena.

Despite the general interest of the newer applications of geographic profiling, and their direct implications for the safety and security of different human populations, there is another significant implication of this more recent research. Though there are many serial criminal investigations that allow for more data to be available to refine the practice of geographic profiling, waiting for another set of serial homicides, for example, is not the most pleasant way of thinking of future data. If, and it does appear to be the case, the predatory behaviors of other animal species are similar to ours, this new research can be used to better understand the predatory behavior of humans. For example, if humans, similar to sharks off the South African coast, also reduce the size of their search area as they age, this information may be useful for the ranking of potential offenders in a criminal investigation; in such a situation, it may be possible to solve a serial criminal investigation sooner because of a better understanding of spatial predatory behavior, more generally.

Crime and Place

As mentioned above, spatial criminology as we know it today began almost 200 years ago with the work in France by Quetelet and Guerry. One of the trajectories of spatial criminology over these many years has been the identification of spatial heterogeneity within the common spatial units of analysis of the day. For many years, the standard spatial unit of analysis within this literature has been the neighborhood (however defined) or census tract. One of the great advantages of these units of analysis is the availability of census data for analysis such as with the crime rate and location quotient studies discussed above. Twenty-five years ago, the use of yet another smaller spatial unit of analysis began to emerge, called the microplace – this literature is often referred to as the crime and place literature. These microplaces could be addresses, street intersections, or street segments and became used for citywide analyses because it became apparent that neighborhoods were far from being spatially homogeneous with regard to criminal activity.

From a theoretical perspective in spatial criminology, the microplace makes a lot of sense. Within routine activity theory (Cohen and Felson, 1979), a criminal event occurs when a motivated offender and a suitable target converge in time and space. That convergence, of course, does not occur in a neighborhood, but at a discrete location. In the geometric theory of crime (Brantingham and Brantingham, 1981), criminal events dominantly occur at our activity nodes and the pathways between them, but there are also particular places within these activity nodes where the majority of criminal events will occur. And lastly, rational choice theory (Clarke and Cornish, 1985) posits that criminal events are the result of context-specific choices. That context can vary significantly within a 'neighborhood' such that the context of microplaces will be important for criminal decision making.

The first known research study to systematically investigate the microplace in a citywide analysis was Sherman et al.'s (1989) analysis of predatory crime in Minneapolis. In this study, Sherman et al. (1989) found that 50% of calls for police service were generated from 3% of street segments. This profound concentration of criminal events showed that even in the neighborhoods with the greatest criminal event levels had areas within them that were crime free. Smith et al. (2000) investigated the integration of routine activity theory and social disorganization theory considering the microplace rather than the more tradition census tract or other census-defined unit of analysis. They found that the integration of these two theories was far more successful using the microplace. Weisburd et al. (2004) and Groff et al. (2009) analyzed the microplace in Seattle using trajectory analysis. Similar to Sherman et al. (1989) these authors found that 50% of all criminal events were accounted for by approximately 5% of street segments, over a 14-year period. Moreover, Groff et al. (2009) found that street segments with the same trajectory tended to cluster together.

Some of the more recent research in this area shows the importance of the microplace in understanding the spatial dynamics of crime. Weisburd et al. (2013), in the context of crime prevention, showed that over a 16-year time period 1% of street segments in Seattle represented 23% of all criminal activity across the city. This is an incredible concentration of criminal events in any context. In another set of analyses in Canada, Andresen and Malleson (2011) and Andresen and Linning (2012) revealed how concentrated crime can be in two Canadian cities, Vancouver and Ottawa. In Vancouver,

Table 1 Concentration (within concentrations) of crime, Vancouver and Ottawa, Canada

	Percentage of street segments accounting of 50% of crime	*Percent of street segments that have any crime*	*Percent of street segments with crime that account for 50% of crime*
	Ottawa, 2006		
Commercial burglary	0.55	2.31	23.78
Residential burglary	1.36	4.86	27.95
Total burglary (aggregate)	1.67	6.61	25.30
Commercial robbery	0.01[a]	0.30	27.84
Individual robbery	0.31	0.65	47.66
Other robbery	0.30	0.82	35.93
Total robbery (aggregate)	0.38	1.46	26.10
Theft of vehicle	0.99	4.50	22.02
Total (without double counting)	1.70	9.52	17.87
	Vancouver, 2001		
Assault	1.62	18.75	8.64
Burglary	7.61	39.43	19.31
Robbery	0.84	5.32	15.87
Sexual assault	1.12	2.99	37.32
Theft	2.58	26.79	9.64
Theft of vehicle	5.97	27.11	22.01
Theft from vehicle	2.64	18.75	8.64
Total (without double counting)	5.02	61.42	8.18

[a]Actual value: 0.000823.

2001, 50% of the criminal events under study (listed in Table 1) were accounted for by just over 5% of street segments – an almost identical result compared to the work done at Seattle. This concentration varied by crime type from approximately 1% of street segments (sexual assault and robbery) to almost 8% (burglary). In Ottawa, 2006, the concentrations were even greater: 50% of the criminal events under study were accounted for by 1.7% of street segments, ranging from 0.01% of street segments (commercial robbery) to 1.67% of street segments (burglary) – the average is greater than the range because different crime types have their concentrations at different places.

The second column of Table 1 shows the percent of street segments that have any criminal events. In Vancouver, just over 60% of street segments have any criminal events, whereas less than 10% of street segments in Ottawa have any criminal events. This is an incredible concentration within Ottawa that may be due to the limited number of crime types under analysis, but is noteworthy nonetheless. The last column of Table 1 shows the percent of street segments with any criminal events that account for 50% of criminal events – this column uses column 2 as the base for the percentage, not all street segments in each city. These percentages represent concentrations within concentrations and indicate that there are clearly hot spots of crime within hot spots of crime and that spatial heterogeneity can even be present considering the microspatial unit of analysis.

Future Directions

Crime and its spatial dynamics is a dynamic field of research. Spatial criminology spans a wide range of research activities ranging from the practical analysis of police activities to the more abstract nature of theoretical testing – of course, better refined theories may serve better practical applications. The four subfields of spatial criminology reviewed above are still in their infancy, requiring a lot of future research to better understand the spatial dynamics of crime.

In the context of spatially referenced crime rates, further applications of the Oak Ridge National Laboratory data to investigate its utility in other contexts is in order. Additionally, there are other sources of data that may be used to estimate the ambient population for more appropriate estimates of the population at risk. For example, the SENSEable City Lab at MIT http://senseable.mit.edu uses cellular phone call data to estimate where people are. And with mobile technologies, more generally, using applications such as Facebook and Twitter with location data there are many possibilities to get a better understanding of where the population at risk may be. Moreover, considering data obtained from mobile devices, measurements of the population at risk may be generated for different days of the year and different times of the day. Research on the alternative measures of crime should involve a broader application of the location quotient in order to continue supplementing the more traditional crime rate. Additionally, the crime rate and location quotient are not the only available measures that can be applied to the study of crime and its spatial dynamics. Future research should investigate other alternatives to be found in other disciplines, such as economics or geography.

Future research in geographic profiling should continue to apply its method to counterinsurgency and counterterrorism in order to increase the safety and security of the affected populations. Additionally, the application of geographic profiling to other predatory species may continue to offer insight into the predatory behavior of human (criminal) activity. And lastly, continued research in crime and place will only serve to

provide a better understanding of the spatial dynamics of crime, particularly at the microspatial scale. Future research should continue to apply the microspatial unit of analysis to other contexts, but also use finer crime type classifications. Much of this crime and place research uses aggregate crime types, but the research that does use more detailed crime types has revealed variations along this dimension as well.

Spatial Equity

Richard Morrill, University of Washington, Seattle, WA, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Spatial equity concerns the perceived unfairness of the well-being of individuals and of societies across space. The contested meaning of spatial equity is reviewed and discussed in six example arenas: social inequality (race, gender), economic inequality (income, wealth, opportunities), regional inequality, political representation, location of undesirable facilities, and urban inequality. Analysis of, and the varied reactions to, spatial inequity are discussed.

Spatial equity concerns the perceived unfairness of the well-being of individuals and of societies across space. Not only is the physical environment very uneven in its utility for human activities, the evolution of societies results in marked inequality in access to resources, rights, and rewards. If the degree of inequality is viewed as unfair and perhaps as imposed unfairly on persons and places, societies may adopt standards and institute programs to mitigate inequality, to reduce segregation, to improve mobility and access to resources, and to redistribute real income.

Although most social scientists may not know the term 'spatial equity,' almost everyone experiences it in everyday life. 'Spatial' implies that most of the experienced world, physical and social, takes up room; this has important social consequences. Elements of the natural and social world always have a location in space or a place, just as they do in time. Phenomena also have relationships of distance, spatial interaction, and accessibility with one another, and these attributes shape the causes and consequences of things. 'Space' has structure, that is, institutions and relationships that constrain what and who can be where – in other words, everything and everyone's place on the landscape.

'Equity' is a social construct by individuals, groups, or societies as to the degrees and kinds of inequalities that are acceptable or 'fair' or are unacceptable and 'unfair.' Thus the measure of equity is inescapably bound up with the individual or group position with respect to the basic human dilemma of individual and collective rights and responsibilities. There is no measure of where fair ends and unfair begins; society redefines the line as needed according to custom and law. Classic works include Perin's *Everything in its Place* (1977), Rawls' *A Theory of Justice* (1971) and Harvey's *Social Justice and the City* (1973). The latter was recently commemorated in Merrifield and Swyngedouw's *The Urbanization of Injustice* (1997). On Rawls, see also Clark (1985).

The Meaning of Spatial Equity

Webster defines equity as 'a legal system which supplements statutes or laws to correct, if necessary, its failure to account for what is morally just and fair.'

Societies may deal with questions of equity and fairness in the justice system or via regulations and legislated standards. Thus a 13-year-old may not claim an equity issue in not being allowed to drive, but a healthy 80-year-old can.

The very fact of space implies that the notion of spatial equality (that all parts of space are of the same quality or value) is without meaning; every bit of space is different from every other. For this reason, equity is of heightened importance and difficult to obtain. In economic theory an efficient equilibrium should be equitable as well. Structurally, monopoly and inheritance, for example, lead to inefficient and inequitable outcomes. But space itself may make a structurally efficient pattern geographically inequitable. Consider a common situation of an uneven distribution of people, far denser on one side of a jurisdiction than the other. The most efficient, travel-minimizing location for a public facility will be strongly pulled to the densest core, leaving those in the low-density edge in a highly unequal position (Morrill, 1973).

The physical environment is incredibly diverse, and utterly unequal from place to place and over time in its utility or value to human production, residence, exchange, or enjoyment. For physical, cultural, historic, and political reasons, individuals, groups, corporations, institutions, and societies are similarly diverse, and highly unequal in physical and mental capacity, experience, and mobilization of resources. They are profoundly unequal in their power to structure the landscape, to alter the environment, or to control more valuable locations.

Individuals, groups, and societies are continually aware of their unequal positions in space, which often leads to perceptions of unfairness on the part of the less territorially advantaged (those on the 'wrong side of the tracks'), and on the part of moralists, ethicists, and liberals offended by or concerned with territorial inequality.

Spatial Equity and Social Inequality

Inequality of power and of rewards itself may lead to resentment and a profound sense of unfairness of the social system. At the societal level, the equity issue is the social system itself, and the battles are more structural than spatial; for examples, calls for socialism or communism as the solution for unequal power and wealth, or battles over minimum wages and tax rates. An exception is perhaps the demand for political self-determination of colonies – struggles that were more territorial and cultural than structural.

But within a nation and social system, as in the United States, although many may want to change the system, the majority of U.S. citizens, for example, accept the competitive and individual system and understand that unequal power and wealth are inherent to the system, that the rich and powerful

can and will preempt the 'best places.' Thus a class-segregated society as such is not a spatial equity issue. After all, that poor person may win the lottery! Rather, issues of spatial equity arise when people feel unfairly treated, although they are playing within the rules of the game; when they feel that the rich and powerful manipulate the law itself to get more than the share that their competitiveness and wealth warrant. An example is the conviction of poverty-area residents that since they pay taxes, too, the potholes on their streets should have no lower priority than the potholes on the streets of the rich.

There are many examples of spatial inequality that raise equity issues. Starting at the global scale are historical colonialism and imperialism and contemporary dependency theory, hypothesizing that unfair power relations exploit and impoverish the Third World. Less technologically advanced cultures distrust and fear the power of Western and especially of U.S. culture. Smith (1977, 1994) provides extensive treatment of inequality from the global to the local scale. See also Knox (1975).

Within nations, prominent bases for raising issues of equity include (1) regional inequality, the sense of exploitation of the periphery by the core, or of poor regions by rich regions; (2) unequal access to public facilities and resources; (3) unequal or unfair treatment of areas because of their poverty, wealth, or power; (4) spatial manifestations of the sports analogy that a competitive society should have a 'level playing field'; and (5) spatial aspects of unequal treatment of categories of people because of race, ethnicity, language, religion, lifestyle, and gender.

Regional Inequality

Within the European Union, a dominant part of the budget and a large amount of research and rhetoric are devoted to the issue of lagging regions, built on the perception that it is somehow unfair that some regions are prosperous and growing while others are poor and languishing; that it shows the failure of the system rather than of the region (Kuntzmann, 1998). In U.S. economic history, class struggles often seemed secondary to the resentment of the South and West against the hegemony of the Northeast. In a generally private economy, the United States has a long tradition of regional redistribution via public programs; for example, the Reclamation Act subsidizing irrigation development in the West, federal defense outlays and massive highway programs, the Tennessee Valley Authority and the Bonneville Power Administration, and the Regional Development Commissions were all designed to improve the competitive position of disadvantaged parts of the country (Johnston, 1980). Harrington's classic *The Other America* (1962) raised the nation's consciousness of poverty and helped lead to the War on Poverty.

Efficient market decisions frequently take the form of the closure of factories and consequent community decline, leading to forced out-migration. In these cases, 'pure market' solutions implying the 'shipment' of the surplus labor to growing regions confront the immense nonmarket value of places to their long-term residents, and a strong sense of unfairness arises, that the decline is not the fault of local people (Clark, 1983). Societies often institute a variety of programs to reduce the social and economic costs, such as through subsidies, community purchase of the closed plant, tax forgiveness, or retraining and relocation assistance.

The same principle is applied at the local level through federal or local programs such as slum clearance, public housing, and 'enterprise or empowerment zones,' reflecting a political consensus that the landscape had become unfairly unequal, presumably because of forces beyond local control.

Voting and Representation

In the United States, perceptions of unfairness in representation led to a series of Supreme Court decisions outlawing malapportionment (unequal population per district) and racial gerrymandering that disenfranchised minorities (initial decisions ruled against 'diluting' and 'packing' minority voters, but later rulings forbade gerrymandering to maximize minority representation). Ironically, representation in the U.S. Senate intentionally violated the equal population principle, since every state has two senators, but this inequality was defended on grounds of avoiding unfair domination of smaller by larger states. But gerrymandering that is purely 'political' is allowed and widely practiced.

Overcoming the 'Unfairness' of Nature

As communities develop and compete with other places, perceptions of being treated unfairly by nature may arise. At the international scale, such perceptions may be used to justify invasions and wars. Within countries, governments at all levels spend huge sums to overcome natural limits, so they may compete on that more level playing field. Examples are bridges, tunnels, and artificial harbors built to improve the accessibility of a place to national and global markets.

Access to Public Facilities and Resources

This is the arena for which the word 'equity' is most likely to be invoked, and for which legal remedies may be sought on grounds of equal protection under law (Pinch, 1985). In the United States, until as recently as the 1960s it was the perception and probably the reality that weaker, poorer places among a set of jurisdictions, and weaker and poorer areas within a jurisdiction, were unequally and unfairly treated. Examples of inequitable access to public services and facilities entail the maintenance and quality of utilities and infrastructure, like roads; the location and quality of parks, playgrounds and pools, or of libraries; and the timeliness of police response calls, as if action were a function not of citizenship but of wealth – which it was. As a consequence of a series of court decisions over many years, cities have become far more attentive to more equal treatment across all parts of their jurisdictions, although huge historic inequities remain.

The construction and operation of public transportation systems have similarly been subject to scrutiny, as to the costs and benefits of subsidies to different parts of a region; poor, more transit-dependent districts no longer meekly accept inferior service and equipment. In most of the United States, school districts are a distinct set of governments. District populations are astoundingly unequal in income, and districts in tax bases. In many but not all states, courts have

interpreted state constitutions to mean that all students should have equal access to education, wherever they live. This has resulted in substantial redistribution of resources from richer to poorer districts, as well as to the subsidy of 'remote but necessary' small schools in very isolated communities.

The Location of Undesirable Facilities: Environmental Racism

A different issue of equity arises as to the differential ability of stronger and richer, or weaker and poorer, jurisdictions or parts of cities to ward off undesirable private and public activities. Less advantaged places widely perceive that they have long been and remain dumping grounds for unattractive and even damaging facilities – prisons, halfway houses, incinerators and landfills, and services to the 'less desirable' folks (drug addicts, alcoholics, the homeless); adult shops and theaters; and polluting and noisy factories. If the obnoxious facilities or activities are in segregated racial minority areas, charges of 'environmental racism' may be made (Bowen et al., 1995; Lester et al., 2001).

Poorer and minority areas also perceive also they are treated as tolerance zones for illicit activities and inadequate law enforcement. More generally, these areas are characterized by loss of jobs, retailing, services, and middle-class housing, leading to spatial mismatch between a declining inner city and more affluent suburbs. In more liberal cities and states, a consensus may arise for some degree of sharing the 'burden' of housing the less affluent, as through requirements for 'fair shares' of subsidized affordable housing, even in suburbs. In a very few metropolitan areas, where extreme political fragmentation results in highly inequitable resources for jurisdictions, a sense of injustice and unfairness has resulted in a degree of tax-base sharing, as for police and sewerage services.

Urban Inequality: Unequal Treatment of Categories of People

Many books focus on spatial inequality in U.S. and European cities, including Badcock (1984), Gottdiener (1985), and Katznelson (1981). An influential segment of the intellectual and planning community advocates fairly radical efforts to break down the high degree of racial and class segregation, as through stronger zoning control of settlement. The failed programs of mandatory busing for school desegregation were similarly based on a sense of injustice and on the premise that mixing in classrooms would lead to mixing in neighborhoods. As with schools, current efforts toward class mixing seem unlikely to be a match for the stronger societal forces for segregation. Although men and women are usually residentially integrated, the history of gender inequality resulted in unequal access to opportunities and resources, and in insecurely built environments. And because of this history, the very subject of inequitably gendered landscapes has only recently been studied (Pratt and Hanson, 1994).

Reactions to Spatial Inequity

As most of these examples show, the achievement of greater spatial equity seems limited to those aspects of everyday life in which public resources or facilities are involved. Social intervention in the form of redistribution of resources toward weaker places and areas seems to occur when a social consensus of 'market failure' arises – that the playing field has become too uneven, within the prevailing social order. Within the social system, it proves easier also to address inequities in some arenas of life than in others. Not surprisingly it is less threatening to those on top, usually the holders of wealth, to accept equalizing measures with respect to political participation and voting and social dimensions (race, language, and gender, although these remain highly contested), and even, if rarely, urban housing, than with respect to the truly key economic arena of income, taxes, and inheritance.

In the United States, issues of equity and redistribution were fought mainly at the national level for most of the period following World War II. Since the mid-1980s and national shifts toward the right – that is, toward greater individual than collective responsibility – the arena of action has moved to local and state levels, where coalitions of activist groups have sometimes been able to gain enough power to enact redistributive plans unimaginable at the national level, such as high minimum wages, rent controls, or mandates for affordable housing, in a process that might be called 'pluralist democracy' (*see* Postmodern Urbanism). In other areas and arenas, conservative coalitions stress faith in the market, privileging its efficiency over concerns for equity (Alexiadis and Eleftheriou, 2010). Indeed, the concepts of efficiency and equity are the very symbols of differing ideological stances toward inequality. The treatment of equity (including this discussion) is usually based on a liberal assumption of people's similarity in needs and values – ideas going back at least to John Stuart Mill. The new politics of identity and difference may complicate the meaning and evaluation of equity (Keith and Pile, 1993; Young, 1990).

The Analysis of Spatial Equity

Maps, and now geographic information systems (GIS), have proven highly effective in revealing the structure of inequality in the landscape – patterns of segregation, poverty, concentration of pollution, and unequal access – and have proven essential to convince legislative bodies and courts to address equity issues. A variety of both statistical and mathematical models have been used to measure inequality and its costs and to assess the impacts of policy changes. Awareness of the human costs of spatial inequality may be increased through more ethnographic studies of the situation of individual households.

Recent Developments

In the years since 2000, global capital has triumphed. Development disparities between countries have fallen, even while income inequality within countries has soared. This may have caused suffering and resentment, but not enough to alter the current social milieu. Indeed, social and political intervention with respect to social–spatial inequality (growing and declining, rich and poor regions or parts of cities) has almost disappeared, and even long-standing public enterprises, such as social housing, are being privatized. Thus the analysis of spatial equity has tended to narrow, focusing on environmental

injustice (Callewaert, 2002), transportation system planning (Monzon et al., 2011), and access to public facilities (Tsou et al., 2005). Additional efforts have been applied to measurement, including the importance of scale (Liao et al., 2010) and visualization (Talen, 2011). A few studies have addressed wider social processes, such as Abel et al. (2011) on the effects of gentrification on the poor, and studies of differential access of racial and income groups (Zhao, 2011; Talen, 2001). For health services, race was critical (see, for example, Kaukinen and Fulcher, 2004, on access to HIV services; and Zenk et al., 2006, on mammogram services). But in Ohio poverty was more important with respect to environmental justice (Bowen, 2001). These at least imply that spatial equity is something that should be addressed.

The complexity of the arena of spatial equity can be seen by the disparate reactions to the widespread implementation of 'smart growth' densification on environmental grounds, despite possibly adverse impacts on the less affluent (Pozdena, 2002). Indeed, while governments invoke planning to address social and spatial equity issues, the on-the-ground implementation of planning may often increase rather than reduce inequity.

This article is a revision of the previous article by A.S. Fotheringham, volume 22, pp. 14794–14800, © 2001, Elsevier Ltd.

Abstract

Spatial interaction involves a wide range of flows between nodes: these include human movements (e.g., migration, commuting) and movement of materials (e.g., international trade). These flows are important aspects of urban and regional dynamics. At the regional level, interactions include many modes and types of flow, such as rail, air, highways, and even pipelines. In cities, spatial interaction takes a wide variety of forms and includes commuting to work and travel for shopping and other purposes. This article presents a brief guide to some of the more important aspects of the discoveries and applications in this field. Practical areas include aggregate and disaggregate models for flows.

Introduction

Spatial interaction deals with flows of people or material between places. The level and pattern of such interaction is a reflection of the need for movement (complementarity) and the difficulty or ease of overcoming intervening distance which serves as an impeding factor. In short, people and places matter (push and pull factors), distance matters, and spatial effects such as competing opportunities, clustering, and agglomeration matter. In examining spatial interaction, models can assist in answering some basic questions: How can we observe and measure these flows? Where are the flows coming from and going to? What problems arise in trying to match flows and infrastructure (e.g., congestion in surface transport, high costs for port installation, or environmental impacts of massive airports)?

Generally, the heaviest spatial interaction occurs along certain main lines of connection (trunk lines). Infrastructure is repeatedly overhauled and expanded to accommodate the *positive feedback* from ease of interaction to the demand for interaction between places (often nodes or places in cities). At the regional scale, the explosive growth of volume of flows between cities in the Northeastern corridor of the US dubbed 'Megalopolis' (Gottmann, 1957) has been accompanied by a dramatic drop in time needed for travel between cities (Janelle, 2005). Interaction can also reach critical levels of congestion: roads built for current capacity are congested soon after they open. Within cities, rents and density rise near transit stations. Spatial interaction is an important topic in the field of spatial analysis. Flows between units (zones, cities, nodes, counties) are hypothesized to relate to the sizes of the origins (sources) and destinations (sinks) and are inversely proportional to the intervening distance. This idea had its origins in simple *gravity models* but has progressed to provide a basic foundation for measurement of large-scale movement such as international trade, freight flows, and air passenger transportation. In addition, the topic also covers accessibility, commuting, trade areas, and many other elements involving movement and interaction in cities. Significant recent progress has been made in computing and mapping these measures. Basic texts have provided the elementary introduction to the notation and help to overcome the 'black box' nature of spatial interaction modeling techniques (Fotheringham and O'Kelly, 1989). The flows are also amenable to interactive spatial data analysis and to many types of models (e.g., log linear modeling; Upton and Fingleton, 1985). Additional resources on this topic include reference works on Isard (O'Kelly, 2004), Wilson (O'Kelly, 2010), and the online content of journals such as *Environment and Planning* and *Geographical Analysis*.

Modeling Spatial Interaction

SI models consider flows between origins (i) and destinations (j). Typically, the goal is to understand the flows or trips (T_{ij}) between i and j, and possibly to predict them in a future scenario. In a generic sense, the flows are a function of the spatial separation between i and j, as well as the characteristics of origins and destinations. Most SI models start with spatial interaction flows and treat them as dependent variables; these are modeled with independent effects including (1) a push factor representing the propulsiveness of each origin (e.g., the number of households in an origin zone); (2) a pull factor representing the attractiveness of each destination (e.g., size of a shopping center); and (3) a measurement of the spatial separation between origins and destinations (e.g., time, cost, or distance to overcome).

The end result depends on how we combine these elements and the precise role each element plays in particular specialized types of interaction. Spatial separation is usually measured using time or distance as a surrogate for the cost of overcoming the space between origins and destinations. Distance is used to denote the difficulty (perceived or real) of overcoming spatial separation; often distance is a proxy for the lack of information and decreased opportunity that occur when origins and destinations are widely separated. Distance is clearly not the sole determinant of behavior patterns as people often travel past the nearest available option in order to reach greater variety or better prices. Nevertheless, there has been a dominant concern in the literature with the principle of least effort and on the role of convenience. There is a strong expectation that interaction declines with increases in distance once other factors are controlled. In practice, the parameter used for the partial effect of distance is often written with a negative sign. To avoid

confusion, the reader should understand that, if $t = f(d)$, where t is number of trips or interactions and d is a measure of distance, there are two ways to mark up the distance decay effect. For example, $t = a + bd$ (where $b < 0$) or $t = a - bd$ (where b is a positive number entering with a negative sign). The beginner in spatial interaction models would do very well to understand that, while these two resultants are the same, the literature tends toward the latter means of notation. For example, Wilson's path-breaking work in spatial models frequently includes a function such as $t = \exp(-bd_{ij})$.

Another key factor is the extent to which data are treated as observed exogenous effects or are developed from within an interaction framework. To make this idea clear, suppose we *observe* a lot of interactions between counties. We could add up the observed interactions *leaving from* or *arriving at* each county and use these observed totals as controls on the values of any modeled estimate. If the estimates are arranged in a matrix with rows representing origins and columns representing destinations, we would logically require that the observed values control the marginal total of the *estimated* matrix. In other words, we could measure interaction and then take some care to make the model reproduce these data in aggregate, through a numerical balancing process called biproportional matrix adjustment. Another key departure is when we have some inconsistent measure of trip propulsion (from origins) and attraction (to destinations) from an independent set of proxy variables. The model framework can be set up to tolerate these inconsistencies quite well and will make estimates maximally consistent with the known data. In this case, the push and pull factors can be used as covariates that tip the interaction in one way or another but that are not strictly required to serve as controlling or constraining totals. This is a subtle but important distinction. When we use data as controls, we need parameters or balancing factors (fixed effects) to make sure our model adjusts to match these data. When we have exogenous surrogates that are trending in the data, we can use them as covariates (perhaps with associated signs that are calibrated if we can study these ideas using some observed data) but not as firm constraints.

To be clear, any time that an origin (by convention row i), or a destination (by convention column j), is unconstrained, the model is free to have such a variable act as a push or pull factor modifying the flows as a form of covariate. In fact, distance is such a covariate. It does not necessarily serve as a constraint on the interactions, but the higher and lower values of distance are expected to have a predictable role in the levels of these interactions. The actual strength of that effect is parameterized by a distance decay effect usually denoted with the Greek symbol beta.

These various types of SI models belong to a family (Wilson, 1971) (**Table 1**); instead of a series of ad hoc parameterizations of effects, the same models (with or without certain individual constraints) may be driven toward some special cases, often matched quite well to the substance and dynamics of the real world problem. For example, in the case of residential mobility, one could imagine a very short-term view where the places of residence and work are fixed and the only adjustment is the journey-to-work path. In the medium term, people are located in a fixed home, but could potentially readjust their place of employment residence. Finally, in the longer term, workers could consider both their residence and workplace locations as flexible.

In what follows, we present examples of three types of models: unconstrained (often used for migration 'M'), production constrained (often used for retail sales 'S'), and doubly constrained (often used for commuting trips 'T'). The decision to treat certain effects as fixed or as covariates needs to be considered carefully for each particular case. Nevertheless, this presentation gives a modern view of the ways that the models are linked without repeating well-known textbook treatments of constraints. There is a fourth model class which is highly similar in structure to the production constrained case (attraction case), but in the interest of a compact explanation, it is not reviewed here.

Migration

One way to write *The Unconstrained Model* is as

$$M_{ij} = f(V_i, W_j, d_{ij})$$

where M_{ij} is the number of migrants that begin at origin i and end at destination j, V_i represents an origin attribute that is a surrogate for the number of migrants beginning at i, W_j represents a destination attribute that is a surrogate for the number of migrants ending at j, and d_{ij} represents the spatial separation (assumed here to be measured by distance) between origin i and destination j. In fact, V_i and W_j can represent vectors with several key variables. **Table 2** (based on Fotheringham and O'Kelly, 1989) summarizes the types of directions in which these specific factors are expected to affect migration. In **Table 2**, V_i is used to represent six independent variables and W_j represents eight (as an example).

Within the origin zone, the number of people, cost of living, crime rate, and unemployment rate are all expected to be positively correlated with values of flows (push factors). On the other hand, the level of amenities and wage rate within the origin zone are expected to be negatively correlated with values of flows (negative push, i.e., retention factors). Typically, reversed patterns occur at the destination end. The hypothesized relationships between these attributes and the origin or destination values have generally been confirmed in many empirical studies. The positive sign relating number of people with both origins and destinations may seem contradictory since the same variable which explains the 'push' away from a zone will also explain the 'pull' of flows into a zone.

Table 1 Models for spatial interaction

	Production constrained	*Attraction constrained*	*Doubly constrained*
Origin	Model matches O_i	V_i as a covariate	Model matches O_i
Destination	W_j as a covariate	Model matches D_j	Model matches D_j
Balancing factors	A_i	B_j	A_i and B_j

Table 2 Typical empirical effects on migration (based on Fotheringham and O'Kelly, 1989)

Migration attribute of origin (push)	*Relationship* dM_{ij}/dV_i	*Migration attribute of destination (pull)*	*Relationship* dM_{ij}/dW_j
1. Number of people	+	1. Number of people	+
2. Cost of living	+	2. Cost of living	−
3. Level of amenities	−	3. Level of amenities	+
4. Crime rate	+	4. Crime rate	−
5. Wage rate	−	5. Wage rate	+
6. Unemployment rate	+	6. Unemployment rate	−
		7. Average house price	−
		8. Average temperature	+

Important early work on this topic at the Leeds School (Cordey-Hayes and Gleave, 2005) has confirmed that migrants in a city have a shorter duration of residence and may therefore be prone to another move or to return migration. These feedback effects are known to require a more elaborate estimation effort (Muth, 1971). The heavy attraction of a city for migrants also presumably pushes up the demand for housing and can make the attractive destination have a higher house price, an effect noted by Congdon (2010). Generally, his results confirm the statistical expectations in **Table 2**. Recent research on this problem continues, and scholars have emphasized the need to correct for biases that arise when key effects are omitted. Often what appear to be contrary results can be corrected and reconciled through the use of more elaborate specifications and more careful assumptions about process. Care is certainly required when the models are deployed in situations with added complexity. For example, regional migration within Mexico is clearly influenced by proximity to the US border (Peeters, 2012). These techniques have been deployed on some massive regional movements such as interregional movement and migration in China (Shen and Wang, 2012).

Retail

Spatial interaction to retail centers involves a fixed pool of demand at the origin and distributes that demand over a set of predefined retail locations. As such, the SI model is an ideal method for the estimation of probabilistically determined trade areas (as opposed to more deterministic methods such as Voronoi diagrams). The long tradition stemming from Reilly's law of markets allows the mapmaker to divide the territory between towns into trade regions or catchment areas. A particularly useful version of this problem is the weighted Voronoi diagram which combines the spatial separation due to distance decay and the attractive weight of the nodes (masses) (see O'Kelly and Miller, 1989).

Issues of spatial choice and sampling also intersect heavily with this topic. Because it is generally easier to collect a sample at the choice-based level (interviews at a shopping center, for example, rather than attempt to find shoppers for a destination in a random stratified sample), the issue becomes one of rescaling a choice-based sample to give a general idea of the probability of a respondent selecting option *j*. This is an exercise in Bayesian analysis. We would like to know how a consumer is attracted to the various options as they are spatially arranged – and whether this is influenced by the cluster or agglomeration effects (see Fotheringham's theory of competing destinations). Because of the relatively large range of choice that the consumer may face, including online purchases, and conversely the large range of origins from which a store draws demand, there is some technical challenge to visualizing the territories. It may be possible to show multiple attractions as a 3D graphic, or it may be easier to draw one map with isolines (contours). O'Kelly (2001, 2009) has provided an extensive review of retail location using spatial interaction tools.

In terms of the expected empirical effects, there are some common sense findings: The origin demand side is strongly related to income and family size (Bawa and Ghosh, 1999). Similar research has been performed by Fox et al. (2004), which divided the stores into different categories such as drug stores, grocery stores, and mass merchandisers. The results indicate that, as expected, income and family size have positive relationships to shopping expenditure. Given that pool of expenditure, the destination attractions are related by spatial models. Oppewal and Timmermans (1997) examine the effects of shopping center size and store variety on destination choice. This literature focuses on modeling the destination attributes such as price, product quality, service, and location accessibility. A logit model (a form of discrete choice model closely related to spatial interaction concepts (Anas, 1983)) is made for two categories of stores: food centers and clothing/shoes stores. The results quantify the way in which shopping expenditure is significantly influenced by selection attributes such as available variety and quality of goods, as well as the appearance and layout of the stores.

Commuting

Prior to innovative work by Wilson (1971) empirical analysis tended to focus on either employment or residential data and to view these two types of data as potentially inconsistent or, at the very least, difficult to reconcile. The spatial interaction representation of journey-to-work provides a means to *connect* these two aspects. The flows originating at zone *i* and destined for zone *j* are arranged in a table (T_{ij}) where the rows of the table point to origins and the columns represent destinations. In database terms, the spatial interaction matrix provides a pivot table (or a cross-walk) to link the origins and the destinations of the trip makers (O'Kelly et al., 2011).

Commuting and interaction involve a complex set of relationships among average journey length, the degree of randomness or organization in the pattern (entropy), and a distance decay effect typically measured by 'beta.' Peak travel during AM and PM rush hours accounts for the highest concentration of traffic on the highways around large metro areas. Significant variations in the lengths of these journeys by gender and by socioeconomic status have been noted (Sang et al., 2011). The data also are fraught with issues of openness of the system: for example, a large regional hospital might employ individuals from a multicounty region. The trips come from an area that far exceeds the immediate vicinity of the hospital. (See a case study concerning Rochester, Minnesota, home of the Mayo Clinic – Sang et al., 2011.) Such commuting patterns also have an important impact on the morphology of edge cities – where the ebb and flow of traffic required by the spatial separation of places of work and residence often stimulate congestion at places that are far from the traditional CBD core (O'Kelly and Mikelbank, 2002). Inevitably, spatial effects are influenced by the somewhat artificial placement of zonal boundaries (Putman and Chung, 1989). Cross-border effects arise as spatial interaction is an open system concept and intrinsically involves flow. It is difficult to put a line of demarcation on a map and say that all trips originating inside a region terminate inside the same region (they may in fact leak out).

Intensive interactions of this kind can place enormous stress on urban transport infrastructure (Hanson, 2004) especially in the absence of significant share using modes other than single occupancy vehicles. There is also a mismatch in the locations of places where entry-level jobs (which might be attractive to certain work force participants) in the logistically advantageous beltway locations and the more dense pockets of urban dwellings (old inner city suburbs). Lack of convenient public transit options linking these places is problematic. Such imbalance between work and home locations is referred to as a spatial mismatch and has raised a host of related issues (Kain, 1992). In addition to the concern for excess commuting where people may be driving across the city to reach suitable employment (O'Kelly and Niedzielski, 2009), such commuting could potentially require many hours of driving in congested traffic or riding public transit.

Calibration

A number of interrelated but separate tasks – and a suite of related techniques for these tasks – is generally referred to as calibration: (1) observe and measure current conditions (description); (2) understand flows as they are observed (how do interaction levels compare to benchmarks or expectations?); (3) produce a model from a limited number of relevant 'explanatory' variables (forecast); and (4) manipulate the expected flow in terms of forecasted changes in exogenous variables (sensitivity analysis). Plenty of challenges arise from the intrinsic unpredictability of behavior, the difficulty of forecasting exogenous variables, and the openness of the systems at hand. Experiments have continued to refine the design of empirical studies of spatial interaction; indeed, the richness of the problem is that it leaves open the possibility of new and improved approaches.

Spatial interaction, as discussed, has a variety of components that are treated as fixed effects (and require a multiplier or balancing factor for each case) or may include covariates that act as weights. There are, therefore, distinctive roles for computation. One aspect of the calibration of such models is to make sure that the balancing effects reproduce the required control totals within a high degree of accuracy. Other parameters are needed to make sure that the model replicates broad aspects of the data. Calibration is well suited to the general problem of fitting log linear models (Tiefelsdorf and Boots, 1995). A good amount of attention also has been given to this topic by Upton and Fingleton (1985). In simple terms, calibration is designed to make the model reproduce some features of the observed data. Often this can be framed as a maximum likelihood problem. Associated with the idea of maximizing likelihood is a set of conditions (first-order necessary conditions) which can be framed as a set of nonlinear equations. As is well known in numerical methods, the solution of a system of nonlinear equations requires that the equations be set up consistently and possess a feasible solution. Single-variable versions of these problems are amenable to graphic solution, but multivariate problems require some computerized implementation with a nonlinear equation solver. A purpose-built method for this is SIMODEL (see discussion in Fotheringham and O'Kelly, 1989), and more recently the data handling capability of MATLAB has allowed many analysts to code their calibration routines in that language.

The prevailing method has included a variety of biproportional matrix adjustments. Biproportional matrix adjustment is the idea that the balancing factors are swapped back and forth – first fixing one and solving for the other, then fixing that one and solving for the first one, and so on. This iterative method usually will yield a set of parameters that maintains the origin (row) and destination (column) totals quite well. The other covariates are bit more complex. One might imagine that the parameters could be adjusted to get a high R^2, but in fact, subsequent theoretical development with a broad range of numerical practice shows that the correct approach is to find maximum likelihood estimates. This means that the parameters are chosen (numerically) to make the model reproduce these observed features of the data. For example, if we observe a mean or a variance, there may be a parameter that will be required to adjust for this. Except in very special circumstances, these parameters cannot be simply computed from the data and need to be determined by numerical iteration. Other special cases are found by solving related optimization problems such as linear programs. Finally, recent research has opened the interpretation of the sensitivity of parameters to changes in the data (O'Kelly, 2012).

Accessibility (Spatial Choice)

Mapping accessibility has a long history in geography. By focusing attention on the ways in which distance and sizes of places confer an uneven surface of opportunity, accessibility maps convey a strong contrast between core and peripheral locations. The evolution of new forms of interaction and the construction of a massive amount of transport infrastructure have tied these regions together, but despite the time–space

convergence reported by Janelle (2005), it remains difficult to overcome the disadvantages of a peripheral location. Aggregate and microaccessibility are two different scaled approaches to the measurement of accessibility. At the macrolevel, O'Kelly and Horner (2003) show how to incorporate the level of access to a place on the basis of its surrounding populations. These maps are direct descendants of the foundational work by Harris (1954) and provide a panoramic view of a national level of accessibility. Such concepts have been adapted to map, for example, the level of access and spatial integration of regions to the Internet backbone infrastructure.

In a widely cited review, Kwan et al. (2003) consider recent advances in representational issues in applied methods for accessibility. Such a microapproach is useful in realistic consideration of spatial choice. For example, when assessing the relative merits of alternative destinations, or of alternative spatial options (such as apartments), one might take into account space and time accessibility to potentially important locations in the urban area. Such measures of potential path accessibility with the temporal and spatial domains combined have been a fruitful area of analysis for geographers interested in individual accessibility. To give one concrete example, a free community clinic with specific opening hours and a location on particular bus routes would be accessible to a range of places that can reach the clinic. On the other hand, it is relatively unhelpful to a neighborhood separated from the clinic by a freeway and without convenient transit options.

The idea of a choice set can be operationalized by emphasizing the places that are readily accessed by various modes of transport and by taking into account detailed information such as opening hours and specific services provided. Indeed, geographical databases have evolved greatly from the earlier work on these issues, and now it is common for published research in the area of spatial interaction to combine a great deal of detailed information about the destinations (the supply side), the origins (the consumer demographics), and the intensity of interaction. Such measures might be obtained from logs of GPS data or by volunteered information from monitoring of the subjects' individual movements. While the foundations for such ideas go back a long way in geographers' analyses of spatial interactions, the newest studies tap an unprecedented level of salient information about individuals. In this regard, many of the limitations of older studies that stemmed from the shortcomings of travel diaries, or lack of microdata, and indeed crude spatial representation have been overcome. In short, this is a time of opportunity for spatial analysts to combine data with many rich conceptual schemas.

Spatial Mismatch

Sara McLafferty, University of Illinois at Urbana-Champaign, Champaign, IL, USA

Abstract

In many American cities, residential segregation and the suburbanization of job opportunities combine to reduce geographical accessibility to employment for African-American, inner-city residents. This 'spatial mismatch' is generally thought to be an important cause of the high rates of poverty and unemployment in inner-city neighborhoods. This article examines how researchers evaluate spatial mismatch; the impacts of spatial mismatch on employment and earnings; the roles of transportation access, racial discrimination, and spatial job search in spatial mismatch; and the variation in mismatch across metropolitan areas. Strategies to ameliorate spatial mismatch, including housing, transportation, and economic development policies, are also discussed.

Spatial mismatch describes a broad set of geographical barriers to employment that stem from a disparity, or mismatch, between where people live and where appropriate job opportunities are located. A more specific form of spatial mismatch, the spatial mismatch hypothesis (SMH), argues that the combined effects of residential segregation and economic restructuring limit geographical access to employment opportunities for African-American, inner-city residents. This article emphasizes geographical dimensions of spatial mismatch, highlighting the changing spatial distributions of residences and job opportunities in cities; the measurement of geographical separation between the two; the social, economic, and spatial processes that underpin spatial mismatch; and policy implications.

Spatial mismatch is a historically specific concept that emerged in the 1960s amid widespread concern about racial discrimination and urban poverty. Although he never used the term 'spatial mismatch', John Kain (1968) introduced the concept in analyzing the combined effects of residential segregation in housing markets and the postwar suburbanization of jobs on black unemployment. Poor geographical access to jobs, especially jobs in manufacturing, was said "to reduce employment opportunities of Negroes who are already handicapped by employer discrimination and low levels of education" (p. 196). Although some subsequent researchers have defined spatial mismatch in narrow geographical terms, as long distances to jobs or small numbers of locally available jobs, Kain's research was notable in exploring the intersections between spatial and social barriers to employment. He considered how transportation access, employer discrimination, skills, and social networks affect workers' access to employment. These themes persist in the spatial mismatch literature.

Kain's hypothesis stimulated discussion and debate during the early 1970s. After that, the field languished for a decade until William Julius Wilson's research on the urban underclass brought spatial mismatch back to the forefront (Wilson, 1987). Since then, the SMH has attracted research attention in a wide range of social science disciplines. It has also been expanded to encompass geographical barriers to employment for ethnic minorities, immigrants, and other potentially vulnerable populations (Ellis et al., 2004; Liu and Painter, 2012).

Evidence of Spatial Mismatch

The great appeal of the SMH is that it connects two prominent features of postwar American cities: the strong segregation of residential areas by race and ethnicity and the movement of jobs, especially jobs in manufacturing, to the suburbs and overseas. But do these processes necessarily result in spatial mismatch? Many central cities are not only losing employment, but they are also losing population (Stoll, 1999). Thus, the balance of jobs to resident workers has remained relatively constant. Although the SMH emphasizes city–suburban differences, fine-grained patterns of residential and work location are much more relevant to job access. Cities and suburbs are not homogenous; within each, African-Americans and other ethnic minorities are concentrated in specific areas reflecting the persistence of racial and ethnic residential segregation.

A key measure of spatial mismatch is job availability – the number and proximity of jobs in relation to the resident workforce. Within central cities, black neighborhoods generally have a lower ratio of jobs to resident workers than do white neighborhoods, although the findings are highly sensitive to the sizes and boundaries of geographical areas used for measurement (Holzer, 1991; Stoll and Covington, 2012). Better metrics have been developed for estimating job availability, including the number of jobs within a reasonable commuting radius of residential zones, spatially defined jobs to worker ratios, and gravity-based measures that incorporate the frictional effect of distance on job access. The plethora of metrics has yielded diverse and often contradictory findings, with some studies uncovering evidence of spatial mismatch, as reflected in the lower availability of job opportunities in and near predominately black neighborhoods (Ihlanfeldt and Sjoquist, 1998), and other studies finding little evidence of racial disparity (Hellerstein et al., 2008).

Researchers have also combined the power of geographic information systems with detailed urban databases to compute new measures of employment accessibility (Houston, 2005). Transportation routes and physical and social barriers to movement are layered together with the uneven geographies of job opportunities and racially segregated residential areas, to describe the multifaceted influences on spatial access to employment. Recent applications also incorporate spatial and temporal elements including public transit availability, the

timing of transit schedules, and time–space constraints linked to everyday work and child care commitments (Rogalsky, 2010).

Commuting times and flows have also been widely used in evaluating spatial mismatch. African-American workers have longer commute times on average than do comparable white workers, and the differences persist after controlling for wages, mode of transportation, and personal and household characteristics (McLafferty and Preston, 1996). Black workers are also more likely to have 'constrained' work trips that involve long travel times to low-wage jobs (Johnston-Anumonwo, 1997). The propensity to work in one's local neighborhood – local working – is also low in black neighborhoods (Immergluck, 1998). Spatial mismatch, then, is evident in long work trips to jobs that provide little economic return.

Although the time and cost of commuting are important in their own right for workers' employment outcomes, they have several limitations as measures of spatial mismatch. By definition, the measures are only based on a selected group, namely, employed workers. This 'selection bias' implies that commuting indicators may not accurately represent geographical barriers to employment for the unemployed (Cooke and Ross, 1999). One way to address this problem is to analyze changes through time as people and jobs move away from central city locations. The impacts of such moves on workers are complex and context dependent. Case studies reveal that when firms move to the suburbs, black workers typically are more likely to quit, more likely to endure longer commute times, and less likely to relocate close to the firm's new site than are comparable white workers (Fernandez, 2008; Ihlanfeldt and Sjoquist, 1998). Black workers are more constrained in their residential locations, indicating the long-lasting effects of racial segregation and discrimination.

There are also problems in interpreting commuting patterns. Do long work trips reflect individual choices to travel further for high-wage, high-quality employment, or do geographical constraints compel long work trips? Many commuting decisions result from a complex mix of choice and constraints, as people juggle personal and family needs within the spatial and social bounds of daily life (Hanson and Pratt, 1995). These choices and constraints vary between men and women, highlighting the importance of gender in the SMH (Blumenberg, 2004).

Attention is turning to the role of place in spatial mismatch and the important variations in spatial mismatch within and among cities and countries (Houston, 2005). In the United States, spatial mismatch is primarily a large-city phenomenon that is most evident in cities like New York, Chicago, Atlanta, and Los Angeles. It is also more apparent in the 'rustbelt' cities of the Northeast and Midwest where economic restructuring and suburbanization are in full force (Ihlanfeldt and Sjoquist, 1998). Less has been written about spatial mismatch in racially and ethnically diverse cities outside the United States, although there are signs of mismatch in cities like London, Johannesburg, Guangzhou, and Berlin where ethnic minority populations cluster in areas of limited job opportunity.

Spatial Mismatch and Labor Market Processes

Spatial mismatch is rooted in the social, economic, and spatial processes that shape urban labor markets. These influence where people and firms locate, the channeling of workers into certain types of occupations, workers' ability to search for and commute to job opportunities, and firms' willingness to hire workers (Gobillon et al., 2007). Connecting spatial mismatch to employment outcomes requires an understanding of labor market processes, as well as an understanding of the changing geographical patterns of firms and people.

Urban labor markets are strongly differentiated according to gender, race, ethnicity, and class. This labor market segmentation concentrates blacks and Latinos in a narrow set of occupations, and the particular occupations vary with gender. Historically, black men worked as laborers, in transportation, manufacturing, and certain service occupations, whereas black women were concentrated in domestic service. Although these occupations have changed over time, there continues to be strong segmentation by race and gender. Moreover, many ethnic minority groups exhibit similarly high levels of occupational segmentation. Segmentation implies that groups of workers living in the same neighborhood who are socially diverse face different sets of potential job opportunities. An important theme in spatial mismatch research has been to tease out the geographical linkages and barriers between race-, gender-, and ethnically defined patterns of residential segregation and occupationally segmented employment locations (Wyly, 1996).

Some labor market segmentation results from differences in education and skills that coincide with racial and ethnic divisions. The 'skills mismatch' refers to the gap between the education and skill levels of inner-city residents and the requirements of available jobs. The transformation from a goods-producing to a service-producing economy has caused a loss of low-skill, manufacturing jobs from central cities, while the emerging 'information economy' demands a highly educated workforce. Thus, central cities may be rich in high-skill jobs, but poor in low-skill jobs that fit the educational backgrounds of disadvantaged central city residents. Poverty, poor-quality schools, and social dislocations limit educational achievement in central cities, resulting in the skills mismatch. These spatial and skills mismatches position workers and jobs in intersecting social and geographical spaces to limit employment possibilities.

Transportation is a crucial factor in spatial mismatch, influencing the ease and cost of overcoming distance in traveling to work. American cities are built around the automobile, the most flexible mode of transportation and the one that offers access to the widest geographical range of job opportunities. In contrast, travel by public transit is slow and limited to fixed routes and schedules. For inner-city residents, the hub and spoke design of most mass transit systems are poorly structured for travel to suburban job centers. Because blacks and Latinos have low rates of car ownership and licensing, they are much more dependent on public transit than are their white counterparts. Transit dependence affects all aspects of employment including job search and access to suburban jobs, and it is the single most important determinant of minority workers' long commute times. Some argue that this 'automobile mismatch' is a more serious problem than the spatial mismatch (Grengs, 2010; Taylor and Ong, 1995).

The process of spatial job search is also important to the SMH. People often search for jobs near their homes. As distance

from the home increases, information about nearby job opportunities decreases and the costs of job search rise. Research indicates that blacks and Latinos' job search patterns are centered upon their homes, and they tend to search in fewer areas and areas with weaker employment growth than do comparable whites (Stoll and Raphael, 2000). Social networks play a key part in spatial job search. Racial and ethnic minorities rely heavily on family and friends for finding employment. For low-income, low-skill workers, this may lead to job search in areas of low job growth and poor-quality jobs, thus aggravating the spatial mismatch.

Employer decisions about whom to hire may also contribute to spatial mismatch. Some employers refuse to hire workers who live far from the work site, fearing that the long commute will lead to lateness or absenteeism (Gobillon et al., 2007). Suburban firms' hiring decisions may be biased along racial and geographical lines, reflecting stereotypes about the inability of inner-city minority workers to interact effectively with suburban customers.

Impacts of Spatial Mismatch

Spatial mismatch affects peoples' lives in diverse ways. The SMH emphasizes the effects on poverty, unemployment, and low incomes, but the empirical record is mixed. Perhaps the strongest support for the SMH comes from research on minority youth. For this group, unemployment is strongly correlated with the average travel time to the types of jobs that youth normally hold and youths' proximity to areas of employment growth (Ihlanfeldt, 1992). Minority youth who face long travel times or distances to job opportunities are much more likely to be unemployed than those who have opportunities nearby. Looking beyond youth, research among vulnerable populations such as welfare recipients reveals mixed findings. Some evidence shows that unemployment is highly sensitive to the concentration of low-wage jobs nearby (Ong and Blumenberg, 1998), whereas other evidence points to a lack of association (Sanchez et al., 2004). Although the impacts of spatial mismatch on labor market outcomes clearly vary from one context to another, an extensive review found general support for the SMH, concluding that "the lack of geographical access to employment is an important factor in explaining labor market outcomes" (Ihlanfeldt and Sjoquist, 1998: p. 881).

Others follow Ellwood (1986) in arguing that "race, not space" (p. 181) is the main determinant of poor labor market outcomes. Racial discrimination permeates urban labor markets in the United States, reducing minority employment irrespective of geographical access to jobs. Racial discrimination is often rooted in place, as firms avoid hiring workers from inner-city, minority communities, or use far-flung, racially biased social networks in attracting employees (Kasinitz and Rosenberg, 1996). Critics of the SMH point to examples where high unemployment and dense job opportunities exist side by side. The challenge in examining 'race versus space' is that the two are deeply intertwined: Race is space in the United States. Kain (1968) recognized this in the original formulation of the SMH, noting the tightly interconnected impacts of racial discrimination by employers and discrimination in housing markets on geographical access to employment. Attempts at disentangling the effects of race and space find that both have large and significant effects on employment outcomes (Hellerstein et al., 2008).

The implications of spatial mismatch beyond labor markets are discussed in Wilson's path-breaking work on the urban underclass (Wilson, 1987, 1996). Wilson starts with spatial mismatch and economic restructuring and weaves a rich tapestry that includes the effects on male unemployment, marriage, household structure, and the implications for an array of social issues such as crime, migration, local institutions, and educational achievement. As jobs move away and incomes decline, the ties that bind communities, households, and institutions start to disintegrate. Spatial mismatch is not the only cause of these changes, but it is an important piece of the puzzle.

Spatial Mismatch and Urban Policy

Despite differences of opinion about the SMH, it has played an important role in urban policy formulation for several decades. Policies to address spatial mismatch involve efforts to bring people and jobs closer together or to improve the connections between them. Three general types of policies have been suggested. First, 'economic development' policies aim at expanding job opportunities in and near the areas where disadvantaged minority populations live. These place-based policies include spatially targeted public works programs, and the provision of subsidies, training programs, and infrastructure, to attract new industries and jobs to inner-city areas. The policies go by various names – for example, 'empowerment zones' and 'New Markets' initiatives – and they have had limited success. Many failed to generate sustained, long-term employment because they did not alter the profitability of inner-city locations and benefits leaked out from inner-city neighborhoods to other areas.

Second, 'dispersal' policies aim at facilitating the movement of people to job-rich suburban areas. These strategies focus on enabling mobility in the housing market. Policies include the vigorous enforcement of fair housing laws, the development of public housing in suburban areas, and the provision of subsidies to help inner-city residents move to the suburbs. A good example of the latter is the Gautreaux program in Chicago, which offered housing subsidies to residents of public housing who wanted to move to the suburbs. Careful studies of the impacts from Gautreaux and similar relocation programs reveal little or no improvement in employment outcomes (Chapple, 2007)

Third, 'mobility' strategies emphasize improving inner-city residents' access to suburban job opportunities, rather than changing the locations of jobs or residences. Included here are improvements in public transit to facilitate reverse commuting, creation of car pools and van pools, employer-sponsored transportation from inner-city areas to job sites, and efforts to improve car ownership among the poor. Such policies have immediate and obvious benefits; however, they have never been implemented on a large scale. Also, the most effective mix of policies varies among cities

depending on the density of urban development and the availability of transportation infrastructure.

After decades of experimentation, most analysts agree on the need for multipronged approaches that are sensitive to the particularities of place and context. Furthermore, there is general agreement that spatial mismatch cannot be isolated from the constellation of forces that affect poverty and unemployment. Breaking down the barriers of racial discrimination in job and housing markets, and improving health, housing, and education in disadvantaged communities, could make spatial mismatch irrelevant in the long run.

Looking ahead, the historical specificity of the SMH highlights the fact that spatial mismatch is not a characteristic of particular locations but of particular places where people are disadvantaged based on a combination of race, ethnicity, class, and poor geographical access to work. Changing patterns of urban development, including the gentrification of inner-city neighborhoods and the growth of poverty in the suburbs, coupled with evolving patterns of employment opportunity, mean that spatial mismatch is perpetually recast. Poor and minority suburban residents are more likely than others to live in jobs-poor suburban communities, highlighting a new form of spatial mismatch (Raphael and Stoll, 2010). Today's suburbs may evolve into tomorrow's 'inner cities' as uneven urban development redefines spatial mismatch.

Spatial Navigation

Thomas Wolbers, Otto-von-Guericke University Magdeburg, Magdeburg, Germany

Abstract

Spatial navigation is a fascinating behavior that is essential for our everyday lives. It involves nearly all sensory systems, requires numerous parallel computations, and engages multiple memory systems. This article will present our current understanding of the cognitive processes required for successful navigation and the neuronal systems that support them. In addition, the final section will discuss how navigational abilities change as we get older, a particularly important topic for our aging societies.

Introduction

'The manner in which the sense of direction is sometimes suddenly disarranged in very old and feeble persons, and the feeling of strong distress which, as I know, has been experienced by persons when they have suddenly found out that they have been proceeding in a wholly unexpected and wrong direction, leads to the suspicion that some part of the brain is specialized for the function of direction' (Darwin, 1873).

Being able to maintain a sense of direction as we move about in our cluttered, everyday environments is a fundamental cognitive function that we often take for granted. Mammals rely on spatial cognitive processes for obtaining food, avoiding prey and finding mates. In humans, spatial navigation is indispensable for finding our way in complex environments, planning routes to distant locations, and returning to our hotel after a walk in a new city. As a consequence, when gradually progressing diseases (i.e., Alzheimer's diseases) or sudden lesions to the brain impair navigational abilities, patients often experience devastating effects on their everyday lives (Aguirre and D'Esposito, 1999). In contrast to Darwin's assumption of a circumscribed part of the brain, however, a widespread cortical and subcortical network supports navigational processes. This distributed instantiation is caused by the complexity of navigational functions (Wolbers and Hegarty, 2010, **Figure 1**):

- Spatial navigation is a multimodal process: spatial information relevant for navigation is usually derived in parallel from a variety of sensory cues, including cues provided by the environment (i.e., visual landmarks) and body-based self-motion cues. In addition, symbolic representations such as maps, signs, or verbal route descriptions can also convey spatial information.
- Spatial navigation involves parallel computations: incoming spatial information is not only used to extract various primitives such as position, facing direction, and the position of external objects, but these parameters are computed in multiple reference frames. In addition, executive mechanisms such as route planning, goal selection, etc. also contribute to guiding our moment-to-moment navigational decisions.
- Spatial navigation recruits parallel memory systems: online representations of position and facing direction, etc. interact with long-term memory representations of local views and the overall structure of an environment. In addition, more procedural memories in the form of habitual routes also guide navigation, in particular when we follow particular paths on a frequent basis.

These factors are highly interdependent (i.e., stored memories of an environment can affect sensory experience), and many navigational tasks bridge multiple levels (i.e., path integration involves perceiving self-motion cues and forming a spatial representation). In this article, I will discuss our current understanding of spatial navigation from a behavioral and from a neuroscientific perspective. As key navigational systems in the human brain show profound changes as we get older, the final section will provide a brief discussion of the decline in navigational abilities experienced by the elderly.

Navigation Based on Transient Spatial Knowledge

When we move about in unfamiliar environments such as a city we visit for the first time, avoiding getting lost is a key challenge. To address this challenge, our brain constantly computes information about our location and facing direction and about the position of important objects, even if they can no longer be seen (i.e., our hotel). While these computations are often based on cues provided by the environment (i.e., a salient building), our bodies also register information about the direction in which we have turned or a distance we have just walked. Collectively, these processes provide transient spatial knowledge that can be used for planning routes, even though they also support the formation of long-term spatial memories.

Path Integration and Spatial Updating

When we move about in an environment, one way to keep track of changes in position and orientation is to continuously monitor our body movements, a process known as path integration (Mittelstaedt and Mittelstaedt, 1980). Path integration has been studied extensively in various animal species, some of which can successfully navigate by path integration over large distances (Etienne and Jeffery, 2004). In humans, the most frequently used task to assess path integration abilities is the triangle completion task, which involves moving participants

Figure 1 The complexity of spatial navigation. Schematic depiction of the sensory cues, computational mechanisms, and spatial representations that are involved in forming spatial knowledge and in using it to guide navigational behavior. Figure modified and reproduced, with permission, from Wolbers, T., Hegarty, M., 2010. What determines our navigational abilities? Trends in Cognitive Science 14, 138–146.

along the first two sides of a triangular pathway, and then asking them to return to their starting location on a direct path, thus completing the triangle (Figure 2). Participants are usually deprived of visual and auditory information, demonstrating that path integration is possible based on body-based cues only. These cues involve motor efference copies, proprioceptive feedback, and vestibular feedback about rotational and translational acceleration. However, path integration can also be based on visual self-motion cues as derived from optic flow patterns (Kearns et al., 2002).

Figure 2 The triangle completion task. Participants are guided along two legs of an imaginary triangle before having to return to the start position – on a direct path – on their own. The dashed blue line shows the correct response, the green line an actual response of a participant. Various error measures can be used to quantify path integration performance, i.e., the absolute distance from the starting location, the angular deviation from the correct turning angle or the deviation of the covered distance from the correct distance.

In contrast to many animal species, path integration in humans is only reliable within shorter distances, because errors quickly accumulate, thus producing increasing uncertainty about one's location as the outbound path gets longer. What mechanisms could explain these path integration errors? First of all, seminal work by Loomis and coworkers (Fujita et al., 1993; Loomis et al., 1993) on blindfolded path integration showed that errors predominantly arise from an inaccurate encoding of the outbound path and not from imprecise execution of the homing trajectory. Secondly, path integration performance can be successfully captured by a leaky integration model (Lappe and Frenz, 2009; Lappe et al., 2007, 2011), in which homing errors are driven by two factors: inaccurate processing of self-motion cues (i.e., perceiving a displacement of 1 m as 90 cm) and an inaccurate updating of the positional estimate. Importantly, the latter is dependent on the current position – the larger the distance away from home, the more inaccurate the updating of the positional estimate will be. Thirdly, path integration errors are also driven by biases such as expectations about upcoming trajectories (Petzschner and Glasauer, 2011). An intriguing example of bias is that people perceive self-rotations as being closer to angles of 0°, 90°, 180° than they actually are (Saddala and Montello, 1989), which has been related to the organization of the body into forward–backward and left–right axes. And finally, humans can employ different strategies to solve path integration tasks, which results in differential patterns of error (Wiener et al., 2011): on the one hand, they might try to continuously update the homing vector during

the outbound path; on the other hand, they might store the outbound path as a series of translations and rotations, thus only computing the homing vector at the end of the trajectory. The latter strategy is less vulnerable to error accumulation as estimates for any given segment will be independent of all other segments, thus resulting on smaller homing errors (Wiener et al., 2011).

While path integration is a mechanism to keep track of one's position relative to a location an observer has physically occupied – i.e., the starting location of an outbound path – spatial updating refers to our ability to update the location of external objects. In other words, spatial updating operates on positional codes that have been derived from (visual) perception and that were not occupied by an observer. Constantly knowing where one is relative to surrounding objects is a central feature of situational awareness and readiness to act. For example, when objects go out of view, when people walk without vision in the dark or when, like pilots, firefighters, and deepwater divers, they operate in situations that are rendered visually unreliable and impoverished, efficient behavior crucially depends on accurate spatial updating.

Similar to path integration, spatial updating relies on the integration of body-based and external self-motion cues (Creem-Regehr, 2004). Humans can easily point to targets from a new position after making a turn while blindfolded, even if they have never seen the objects from this new perspective (Farrell and Robertson, 1998). Importantly, spatial updating occurs largely automatically both in real and in virtual environments (Farrell and Robertson, 1998; Riecke et al., 2007; and Wang, 2004). For example, when asked to ignore their movements and to point to the targets as if they had not moved, people show significant costs in response time and accuracy, which suggests that they have great difficulty in voluntarily preventing spatial updating from occurring.

Most experimental studies on spatial updating have used setups with relatively small numbers of objects, making a continuous updating of multiple object vectors a computationally tractable problem. However, additional strategies are likely to come into play when we have to deal with the complexity of our everyday environments. One such strategy is chunking, in which adjacent objects are grouped together and only one prototypical vector per chunk is updated during self-motion (Sargent et al., 2010). Alternatively, when moving about in a complex but familiar environment, humans tend to only update their own position and orientation – using path integration – before reconstructing object positions from the new vantage point (Waller and Hodgson, 2006).

Brain Systems Computing Transient Spatial Information

Our knowledge of the neural systems computing instantaneous spatial information has been fueled by several important discoveries from electrophysiological recordings in freely moving rodents. A key structure for self-localization is the hippocampus, whose principal neurons, the place cells, fire selectively in specific regions of the environment known as 'place fields' (O'keefe and Dostrovsky, 1971) (**Figure 3**). Place cells collectively provide a representation of position, and they receive information both about self-motion and stable environmental cues. For example, at least in rodents, proximal environmental boundaries primarily specify the location of place fields (O'keefe and Burgess, 1996), whereas distant landmarks are important for directional orientation (Jeffery et al., 1997).

Place cells, however, do not provide an absolute spatial signal, as their firing is also modulated by various nonspatial factors such as motivation, goals, etc. As a consequence, it was often speculated that positional information must be computed upstream of the hippocampus, and the discovery of grid cells in entorhinal cortex has confirmed this hypothesis (Hafting et al., 2005). Grid cells are directly afferent to hippocampal place cells, and they exhibit multiple, evenly spaced place fields. The precise position of an animal can be reconstructed from a population of grid cells, and many researchers assume that the unique place fields in the hippocampus emerge from the integration of grid cells with different spatial frequencies (Moser and Moser, 2008). Importantly, in monkeys, grid cell firing has been observed when the animal was merely looking at different spatial locations (Killian et al., 2012), suggesting that in primates – who are equipped with more developed visual systems – computing positional knowledge may not require physical locomotion. Finally, to be able to continuously update positional representations, grid cells must receive information about the direction in which an organism moves. This directional orientation is computed by the head direction system, a network of limbic structures whose neurons, the head direction cells, show directionally specific firing (Taube et al., 1990a) (**Figure 3**).

While the firing of place, grid, and head direction cells is strongly influenced by stable environmental cues such as boundaries and distal landmarks, they also support navigation based on path integration. For example, the periodic firing of grid cells and the directional firing of head direction cells persist even when all visual cues are removed and the animal navigates in total darkness (Hafting et al., 2005; Taube et al., 1990b). Moreover, neural activity in the head direction circuit is closely related to rats' homing direction (Van Der Meer et al., 2010; Valerio and Taube, 2012), and lesions to entorhinal cortex severely disrupts homing performance (Parron and Save, 2004). In humans, corresponding findings from lesion and neuroimaging studies also support the notion that structures in the medial temporal lobe, which contain grid, place, and head directions cells, are involved in path integration (Philbeck et al., 2004; Wolbers et al., 2007; Worsley et al., 2001).

In contrast to the wealth of studies on path integration, studies on the neural systems mediating spatial updating are scarce. Given that subregions of the posterior parietal cortex (PPC) code for spatial location in egocentric reference frames and receive multimodal self-motion cues, theoretical models have predicted spatial updating to be mediated by PPC structures such as the precuneus (Byrne et al., 2007). Lesions to the PPC, however, do not always impair spatial updating performance (Farrell and Robertson, 2000; Philbeck et al., 2000, 2001), but the conflicting findings of these studies may partially stem from small sample sizes and the largely variable lesion locations. More conclusive evidence has been provided by neuroimaging studies that required subjects to update object locations using optic flow (Wolbers et al., 2008

Figure 3 Place, grid, and head direction cells in rodents. (a) A classical place cell. The black lines show the path of a rat as it foraged in a 60 cm square box, and the red squares show action potentials from a single hippocampal neuron, superimposed on the position of the rat. A typical place cell will predominantly fire action potentials in one part of a small environment (the 'place field'). (b) Grid cells from dorsal (upper panel) and ventral (lower panel) dorsomedial entorhinal cortex. The figure shows the hexagonal array of firing fields typical of grid cells. Note the change in interpeak spacing between dorsal and ventral regions. (c) Data from a typical head direction cell, showing that firing rate (*y* axis) increases dramatically when the rat's head is within a restricted directional orientation (*x* axis). Figure reproduced, with permission, from Jeffery, K.J., 2007. Self-localization and the entorhinal-hippocampal system. Current Opinion in Neurobiology 17, 684–691.

(see also **Figure 1**); Jahn et al., 2012). These studies have consistently identified the precuneus as a structure that combines stored representations of external locations with incoming self-motion cues, thus providing moment-to-moment estimates of spatial locations. Importantly, the precuneus supports spatial updating independent of how we plan to interact with our environments, while the dorsal premotor cortex appears to use this information to plan upcoming motor actions (Wolbers et al., 2008) (**Figure 4**).

Navigation Based on Enduring Spatial Knowledge

Although path integration and spatial updating are often discussed as navigational mechanisms, both processes are also integral for the acquisition of enduring representations of space. When we become familiar with an environment, we can navigate to distant goals that involve the recognition of several places and a representation of spatial relations between objects outside the current sensory horizon. Collectively, these processes are often referred to as wayfinding behavior, a multifaceted construct that involves at least two different navigational mechanisms.

Route Knowledge and Cognitive Maps

Wayfinding behavior can be based on route knowledge and on cognitive maps. Route knowledge is often conceptualized as a goal-directed representation of a fixed sequence of landmarks, each of which is associated with a specific movement decision (Franz and Mallot, 2000; Mallot and Gillner, 2000). Navigation based on route knowledge proceeds by approaching environmental landmarks and by then executing the associated movement decisions (i.e., turn right at the church). Route knowledge has often been reduced to a mere sequence of stimulus–response pairs that, in effect, is 'empty' between landmarks (Siegel and White, 1975). It is often assumed to neither contain off-route information nor quantitative properties like Euclidean distances between landmarks (Golledge, 1999). However, because views of landmarks can prime upcoming landmarks, route knowledge also contains information about the temporal sequence of landmarks, but only in the direction in which the route was learned (Schweizer et al., 1998).

It is important to note that route knowledge not always provides associations between landmarks and movement decisions. Depending on the configuration of the environment, landmarks can also serve as beacons. A beacon specifies a goal location without being associated with a particular directional movement (i.e., go to the church or turn toward the post office). In this case, route knowledge is reduced to a mere sequence of beacons (i.e., first go to the church, then to the post office, etc.), which is a parsimonious knowledge structure. As a consequence, while routes are learned better when their landmarks serve as beacons than as associative cues, beacon-based route knowledge is less enduring and less likely to involve knowledge of directions in the environment than is the route knowledge formed from landmarks that serve as associative cues (Waller and Lippa, 2007).

Cognitive maps – often termed survey knowledge or configurational knowledge – constitute the most elaborate and flexible form of spatial representations. These representations embed the objects in an environment and their spatial relations into a common reference frame that is independent of the observer. Moreover, survey knowledge is thought to contain quantitative information about distances and angular directions. The term cognitive map was first coined by Tolman (1948) to express that rats in his experiments took novel shortcuts to a goal location, thus indicating an understanding of the spatial structure of the environment. The term suggests – and is often used to suggest – that we

Figure 4 Neural mechanisms of spatial updating. Upper panels: in the study by Wolbers et al. (2008), participants underwent fMRI scanning while performing a spatial updating task in a virtual environment. The task required participants to first memorize the locations of 1–4 virtual objects that subsequently disappeared. In the ensuing delay phase, subjects either remained stationary (static trials) or they experienced a forward translation of a random distance. At the end of the trajectory, participants had to point with a joystick to one of the objects shown before. Lower panels: during the delay phase, only the precuneus showed activation profiles that were modulated (a) by the number of objects that had memorized and (b) by the presence of self-motion cues (updating). These data suggest that the precuneus uses incoming self-motion cues to continuously update egocentric object positions. Figure modified and reproduced, with permission, from Wolbers, T., Hegarty, M., Büchel, C., Loomis, J.M., 2008. Spatial updating: how the brain keeps track of changing object locations during observer motion. Nature Neuroscience 11, 1223–1230.

possess spatial representations similar to a real map, as if the world was represented from a bird's eye perspective. However, there is currently no direct evidence to support this claim, and many researchers (i.e., Thorndyke and Hayes-Roth, 1982) prefer to think of cognitive maps as 'see through representations' that preserve the ground-level perspective but in which distant locations can be accessed through intervening points (i.e., buildings).

A key feature that distinguishes cognitive maps from route-based navigation is that only the former enable flexible navigational behavior: whereas route-based navigation is only effective along the represented paths, survey knowledge can be used to find novel paths over unknown terrain and between unconnected routes, to take shortcuts and to point to unseen landmarks. According to influential models of spatial learning, both types of knowledge develop in a series of sequential qualitative transitions, from initial landmark knowledge to representations of routes and finally to flexible survey knowledge (Hart and Moore, 1973; Siegel and White, 1975). Landmarks are conceptualized as discrete objects or scenes that are stored in memory and recognized when perceived. Other than the local spatial information that is present in a scene, landmarks do not contain any spatial information. Once acquired, landmarks are then associated movement decisions and connected into chains that preserve the order experienced during navigation. These chains are the constituents of route knowledge, the second stage of spatial learning. The integration of different routes into a single representation along with metric information constitutes the final step, the formation of survey knowledge.

Recent evidence casts doubt on this strictly hierarchical conceptualization of environmental learning. For example, Ishikawa and Montello (2006) had subjects learn an environment while being driven in a car. The authors found that whereas some participants failed to develop survey knowledge even after 10 learning sessions, others had acquired at least partial metric knowledge already after the first exposure to the environment. More importantly, metric judgments about route distances were often better than when subjects had to rank order the route distances. This inferior ordinal accuracy suggests that forming a precise route representation is not a necessary precondition for the development of survey knowledge. In addition, the ability of humans and various animals to perform path integration tasks indicates that some metric knowledge about turning angles and the lengths of path segments is already present after single trial learning. As these empirical results are difficult to reconcile with hierarchical concepts, alternative models of spatial learning argue for a potential to acquire survey knowledge from the very beginning of a learning experience (Montello, 1998). In addition, the evolution of landmark, route, and survey knowledge might rather proceed

in parallel, although the latter seems to only emerge in subjects with a good sense of direction (Ishikawa and Montello, 2006).

Brain Systems Mediating Route Knowledge and Cognitive Mapping

Given that route knowledge is usually conceptualized as chains of associations between local views of an environment and specific motor responses, it comes as no surprise that brain structures classically associated with scene processing (parahippocampal place area (PPA)) on the one hand and with procedural learning (striatum) on the other hand have also been implicated in route learning. For example, objects encountered at intersections, which require a decision about where to go next, elicit larger activation in the PPA than objects encountered along the way (Janzen and Van Turennout, 2004). In addition, neuroimaging studies have shown that activation in the caudate nucleus is predictive of route retrieval accuracy (Hartley et al., 2003), and subjects who use a response-based strategy showed larger caudate activation than subjects who adopt a cognitive mapping strategy (Iaria et al., 2003). Interestingly, when the caudate is dysfunctional (i.e., as in Huntington's disease), compensatory activation in the hippocampus still allows for successful route negotiation (Voermans et al., 2004).

These studies, however, do not distinguish between routes learned as stimulus–response associations versus a series of beacons that do not need to be associated with specific movement decisions. Anatomically, the striatum is not a unitary system, but there exists a functional dissociation between the medial/ventral and the lateral/dorsal striatum (Voorn et al., 2004). The ventral and dorsomedial striatum receives extensive convergent input from multiple sensory and association areas of neocortex and the limbic system, while the dorsal and dorsolateral striatum has a distinct topographic pattern of connections with somatosensory and motor areas of neocortex (McGeorge and Faull, 1989). These findings could indicate that the dorsal and dorsolateral striatum – which comprises the caudate nucleus – is more important for motor response learning as required for stimulus–response associations, whereas the dorsomedial and ventral striatum could be more important for beacon strategies. Indeed, lesion studies in rodents implicate the dorsolateral striatum in stimulus response learning (Packard and McGaugh, 1996). Moreover, there is evidence that the dorsomedial/ventral striatum does not affect stimulus response learning to the same extent as dorsal/dorsolateral lesions (Yin and Knowlton, 2004). Finally, dorsomedial lesions affect the learning of a beacon strategy in the Morris Water Maze (MWM), whereas dorsolateral lesions do not (Devan and White, 1999).

Ever since the discovery of place cells, the hippocampus has been hypothesized to be the neural system that supports flexible, cognitive map based navigation. Specifically, as place cells receive input from grid cells about spatial position along with information about objects, they might store the locations of environmental objects in an observer-independent, allocentric reference system. Consistent with this assumption, rats with hippocampal lesions show profound deficits in the MWM when they need to swim to a location defined by external landmarks (Morris et al., 1982). Even though virtual renditions of the MWM have revealed similar deficits in humans with hippocampal lesions or degeneration (Hort et al., 2007; Goodrich-Hunsaker et al., 2010), it is important to note that the MWM only measures spatial knowledge of a local place. However, a key feature of cognitive maps is that they allow for inferring spatial relations between distant locations that often cannot be simultaneously perceived from a single vantage point, hence the MWM may only be of limited value for investigating large-scale cognitive mapping.

In humans, neuroimaging and lesion studies conducted in large virtual environments have consistently shown that the posterior hippocampus is implicated in retrieving knowledge about familiar environments, for example, when planning and navigating novel routes (Hartley et al., 2003; Iaria et al., 2007). In addition, hippocampal representations appear to contain metric knowledge about distances and directions, strongly suggesting the existence of quantitative cognitive maps in the place cell network (Morgan et al., 2011; Spiers and Maguire, 2007). In line with the plasticity of many cortical networks, the posterior hippocampus is enlarged in expert navigators such as London taxi drivers (Maguire et al., 2006). Crucially, this effect was not observed in London bus drivers who experience similar amounts of stress, self-motion, etc. but who always travel along habitual routes (Woollett and Maguire, 2011). The extensive use of elaborate cognitive maps for flexible route planning in the taxi drivers thus is likely to drive structural changes in the posterior hippocampus. However, given that patients with complete hippocampal lesions can retrieve cognitive maps from environments learned long ago (Teng and Squire, 1999), the hippocampus may only play a time-limited role in storing and retrieving cognitive maps.

The enlargement of the posterior hippocampi in London taxi drivers came at the expense of a reduced anterior hippocampal volume, which was paralleled by a reduced ability to learn novel spatial information. This findings point to a dissociation between the anterior and posterior hippocampus, with the former being mainly responsible for the learning process. To test this hypothesis, Wolbers et al. (2005) had subjects learn the layout of an unfamiliar environment from first-person navigation while undergoing fMRI scanning (**Figure 5**). The most important finding of that study was that activation in the anterior hippocampus predicted the amount of learning: sessions with strong anterior hippocampal activation led to substantial performance improvements, whereas in sessions with low activation, performance hardly changed. Together with similar findings from other groups (Iaria et al., 2007), these results indicate that the anterior hippocampus contributes to spatial navigation by integrating and consolidating novel spatial information such as the relative position of environmental landmarks into observer-independent cognitive maps.

Two further brain structures often implicated in cognitive mapping are the PPA and retrosplenial cortex (RSC). While the PPA has consistently been associated with processing the geometric structure of local scenes in a viewpoint-dependent fashion (Epstein, 2008), the role of RSC is less clear. In rodents, RSC contains head direction cells that provide a compasslike signal by continuously tracking an animal's

Figure 5 Learning cognitive maps. Upper panels: in the study of Wolbers and Büchel (2005), participants were repeatedly moved throughout a complex virtual environment, thereby encountering 12 distinct landmarks. Subjects were instructed to infer the spatial layout of the environment and the correct landmark locations, knowledge that was tested with a subsequent retrieval task. Lower panels: anterior hippocampal recruitment during cognitive map formation predicts the speed of learning. Hippocampal activation (shown in red) in subject 11 was strongest in the initial learning stage and decayed rapidly after performance had reached ceiling level in session 3. In contrast, the slower learning process in subject 03 was paralleled by stronger hippocampal activation in the second half of the experiment. As a consequence, anterior hippocampal activation appears to be most prominent whenever substantial performance improvements are observable. Figure reproduced, with permission, from Wolbers, T., Büchel, C., 2005. Dissociable retrosplenial and hippocampal contributions to successful formation of survey representations. Journal of Neuroscience 25, 3333–3340.

orientation (Cho and Sharp, 2001). Similarly, human patients with RSC lesions can identify familiar places and scenes, but they cannot use them for orientation (Ino et al., 2007; Maguire, 2001). However, a direct demonstration of head direction signals in human RSC is missing at present. Moreover, while some authors emphasize the RSC's role in forming memories of spatial information (Cooper et al., 2001), others assume that any computation that involves translation between ego- and allocentric reference frames requires RSC functioning (Byrne et al., 2007). Importantly, such computations are also needed to form enduring representations of complex environments as shown by neuroimaging studies (Wolbers and Büchel, 2005).

Aging of Navigational Abilities

The world's population is aging at an unprecedented rate. The number of people aged over 60 is set to rise from 784 million in 2011 to 2 billion by 2050 (United Nations, 2012), and a significant proportion will have to cope with normal or pathological cognitive decline. Despite huge efforts to understand the mechanisms of age-related cognitive decline, the number of studies looking at navigational abilities is surprisingly scarce. This is all the more surprising when we consider the following facts:

- in surveys, elderly people often report substantial declines in navigational abilities (Burns, 1999), for example, problems with finding their way in a novel environment,
- navigational difficulties can have a huge impact on the quality of life of the elderly, for example, by affecting social participation and physical activity,
- key brain structures supporting navigational functions such as entorhinal cortex, the hippocampus, and RSC show the earliest signs of age-related neurodegeneration, and
- age-related navigational impairments have been well characterized in nonhuman species, making it easy to generate testable predictions for studies with human participants.

In the aging brain, layer II of entorhinal cortex, which appears to contain the highest proportion of grid cells both in rodents and primates (Hafting et al., 2005; Killian et al., 2012),

is particularly sensitive to the deleterious consequences of aging (Stranahan and Mattson, 2010). Specifically, neurodegenerative changes such as neuron loss occur in the earliest stages of age-related cognitive decline and Alzheimer's disease; hence, disrupted grid cell computations could be among the earliest functional changes in the brain, which should have direct effects on path integration. Indeed, aging humans show profound deficits during walking without vision and in optic flow-based path integration tasks (Allen et al., 2004; Mahmood et al., 2009), and they are impaired at heading perception in virtual environments (Mapstone et al., 2006). Getting closer at the mechanisms that might explain such path integration deficits, older adults have been shown to exhibit a significantly reduced range of responses when asked to reproduce turns and distances and to complete triangular pathways (Harris and Wolbers, 2012). These results can be interpreted in the context of the leaky integrator model (Lappe et al., 2007), suggesting that due to an increased leak in the integration process, stored self-motion information decays more rapidly in old age.

In addition to path integration deficits, aging also affects the formation and use of cognitive maps. Aged rodents show deficits in tasks in which spatial relationships must be computed between environmental cues, while tasks requiring egocentric cues are less affected (Begega et al., 2001). Moreover, even when successfully trained on both place and response strategies, aged mice still show a spontaneous preference for egocentric response strategies, strongly suggesting an age-related increase in reliance on extrahippocampal systems to guide navigation (Nicolle et al., 2003). Such age-related navigational impairments are likely related to the age-related changes of the hippocampal place cell system. Specifically, the spatially localized firing of aged place cells has been shown to take longer to emerge, to be less stable across repeated visits to a familiar environment, and to be less capable of differentiating between familiar and novel environments (Lister and Barnes, 2009).

Similar to rodent findings, difficulties with employing cognitive map based strategies have been observed repeatedly in older humans (Moffat and Resnick, 2002; Moffat et al., 2007; Iaria et al., 2009; and Wiener et al., 2012). For example, older adults tend to disregard distal geometric information in an environment and focus more on local objects to guide navigation (Moffat and Resnick, 2002). Moreover, in the plus maze task, which can be solved with a striatum dependent egocentric response (i.e., go right) or a hippocampus dependent allocentric place (i.e., go east) strategy, older adults show specific deficits in switching to the place strategy (Harris et al., 2012, **Figure 6**). Consistent with these behavioral findings, fMRI studies with virtual renditions of the MWM have shown reduced activation of the medial temporal lobe in old age (Antonova et al., 2009; Moffat et al., 2006). Such findings, however, need to be cautiously interpreted, because an overall reduction of the Blood Oxygen Level Dependent (BOLD) signal may be due to a range of factors (i.e., hemodynamic changes in old age) that may or may not reflect a change in navigational processing.

Given the spontaneous preference for egocentric response strategies in aged rodents and humans, one may expect route-based navigation to be relatively preserved in old age. However, structural neuroimaging studies have shown that the caudate nucleus, a key structure for stimulus–response associations (see previous section), shows age-related neurodegeneration at similar rates compared to the hippocampus (Raz et al., 2005). As a consequence, it comes as no surprise that studies on route learning have revealed deficits in remembering associations between landmarks and directional information (Liu et al., 2011; Head and Isom, 2010; and Wilkniss et al., 1997). For example, Wilkniss et al. (1997) had participants navigate through the hallways of a hospital after being shown a map of the environment and the route they were required to follow. Overall, older adults took longer to navigate through the hospital than younger adults, and they made more frequent turning errors. In contrast, older adults were not impaired at remembering the landmarks encountered along the way, suggesting that simple landmark knowledge might still be useful for navigation.

As stated before, route knowledge can either be based on associations between landmarks and movement decisions, or it can involve a sequence of landmarks serving as beacons, thus not requiring the formation of links with particular movement decisions. Rodent studies suggest that the ventral striatum may be particularly important for beacon-based navigation, and anatomical data have demonstrated that the dorsal striatum may be more vulnerable to age-associated changes than its ventral counterpart (Tupala et al., 2003). Wiener and colleagues (2013) built on these findings to test whether aged humans show a spontaneous preference for beacon-based navigation strategies. Overall, older adults were impaired at route learning compared to a young control group, but even when underperforming older adults were removed from the data, a striking age-related bias remained: when these participants were asked to rejoin the familiar route from a novel vantage point, they overwhelmingly used landmarks as beacons and showed little evidence for forming associations with specific movement decisions. These finding strongly suggest that using landmarks as beacons may be a strategy least affected by aging, which could allow for successful route negotiation in old age whenever an environment provides salient beacons.

One consistent finding of many studies on cognitive aging – not only in the field of spatial navigation – is that performance variability between participants increases with advancing age. In other words, whereas many older participants show striking performance impairments, others perform at levels similar to young control groups. Such findings naturally raise questions about what differentiates people who experience rapid cognitive decline from those who are more resilient to age-related changes. Neuroanatomically, individual trajectories of structural brain changes vary greatly, which has been shown for some structures involved in spatial navigation (i.e., hippocampus, Raz et al., 2005). Whether or not such differences are related to predispositions such as brain size, intellectual abilities, level of formal education, etc. (Steffener and Stern, 2011; Coffey et al., 1999) is currently under intense debate. Moreover, given that navigational abilities are at least partially separate from other cognitive abilities (Hegarty et al., 2006), it will be important to determine whether an individual's general intellectual abilities or more specifically the level of

Figure 6 Impaired switching to an allocentric place strategy in older adults. Upper panels: left: diagrammatic representation of the plus maze task, illustrating place and response strategies, and switch and reversal change types. Right: screen images captured during the virtual plus maze task, at the start point, at the junction before turning, at the junction after turning, and at the goal (showing a reward). Upon reaching the junction, participants have to decide whether to go right or left. Participants need to learn the correct strategy from whether or not they receive a reward at the end of a trial. Strategy changes or reversals occur unbeknownst to participants. Lower panels: plus maze performance in terms of trials correct (left), blocks learned (middle), and stable trials (right) during blocks following switches to the place strategy (S2P), switches to the response strategy (S2R), reversals of place (RP), and reversals of response (RR) for young (red) and old (blue) participants. All three measures clearly show a selective deficit in older adults when required to switch from the response to the place strategy. Figure reproduced, with permission, from Harris, M.A., Wiener, J.M., Wolbers, T., 2012. Aging specifically impairs switching to an allocentric navigational strategy. Frontiers in Aging Neuroscience 4, 29.

navigational abilities may predict the rate of navigational decline experienced in old age.

Concluding Remarks

Ever since Darwin's visionary statement, much has been learned about the numerous cognitive computations that help us find our way in our everyday environments – and the underlying neuronal systems. Nevertheless, cognitive neuroscience research on spatial navigation still is in its early days, and many important challenges remain. For example, probably due to the complexity of navigational behavior, researchers have developed a huge variety of experimental tasks. These tasks are not always well understood in terms of the navigational processes they involve, which is particularly problematic for neuroimaging studies trying to assign specific functions to the activation differences they might observe between different experimental conditions. Secondly, relatively few studies have addressed questions of multisensory integration, even though animal research has clearly demonstrated that body-based cues are important for spatial computations carried out in circuits such as the place cell network. Thirdly, while humans differ in any cognitive ability (i.e., attention, memory), interindividual variability in navigational functioning is probably among the largest of all cognitive functions. Specifically, while some people find it easy to form a mental image of an environment even after just one or two visits, others get lost as soon as they have to leave a habitual route. At present, what differentiates these extremes – i.e., in terms of genetic predispositions or learned behaviors – is poorly understood. And finally, considering the existing animal research on the effects of aging on navigational processes, the low number of studies addressing similar questions in humans is surprising. Spatial navigation is an essential everyday function; hence a precise understanding of navigational impairments in old age is vital for improving the quality of life of our rapidly aging societies. In addition, some of the spatial computations affected by aging are likely to play a role for nonspatial functions as well, hence they could provide a novel window into general mechanisms

of age-related cognitive decline. Harvesting this unique opportunity shall be as fascinating as the topic of investigation – spatial navigation – itself.

Spatial Optimization Models

Abstract

Human activities are often arranged into zones or groups. For example, a town may have a central business district, residential areas, schools, medical clinics, etc. Activity patterns are determined in part by the basic layout. In contrast, a manufacturing plant is designed to have an assembly line or assembly areas, parts fabrication, inventory storage, etc. The layout of any facility helps determine the cost of manufacturing a product, just as the layout of a town helps determine the extent to which various people travel to accomplish daily tasks. The layout or location of all or a subset of such activities is called spatial optimization. This review article describes a number of different spatial optimization problems and concludes with directions for future research.

The concept of spatial optimization is quite simple. This topic involves identifying how land use and activities should be allocated and arranged spatially in order to optimize efficiency or some other measure of goodness. For example, how should fire protection resources be distributed across a city in order to maximize protection? How do we design a system of reserve lands that can ensure the survival of an endangered species? How should an area be divided into school attendance zones? These are but a few examples of spatial design problems. For each type of design problem there can be numerous if not an infinite number of alternative configurations or solutions. Optimization involves the attempt to identify the best of the alternatives. Simply put, spatial optimization is the science of optimal arrangement. The use of spatial optimization is growing owing to the existence of better spatial data, the emergence of powerful geographic information systems, decreasing costs of computation, and better computer graphics and solution algorithms.

At first we might think that such a topic is futuristic, cutting edge. Actually, spatial optimization is a geographical problem that is as old as mankind. For example, hunters and gatherers had to decide how to allocate their efforts in collecting foodstuffs, moving encampments, etc. Such societies needed to be efficient in order to survive. Anthropologists and geographers have used optimization to analyze the efficiency of these early societies (see, e.g., Van Reidhead, 1979). Even the ancient Chinese art of Feng Shui deals with the arrangement of activities in order to be in a harmonious state. Just as we are interested in how spatial arrangements evolved in the past, we are equally interested in how future patterns of activities should be designed and placed, especially to meet sustainability, health, justice, and resilience. For example, just where should that new store be located? Where should a dealer provide service facilities for their products? How should a network of warehouses be designed and operated in order to supply a number of retail locations? What network of supply routes and storage centers best responds with humanitarian aid in disasters such as an earthquake in Sichuan or a monsoon in Bangladesh? Such questions are but the tip of the 'iceberg' of possible spatial location/allocation problems.

As with all geographic problems, the temporal domain is important. For example, Broward County, FL operates a school system with a budget of US$3.1 billion (2013) involving 315 schools and 260 000 students. Every year, a 5-year forecast is made for enrollment at each school. Those schools with a projected enrollment of 95% or more of capacity are then subject to possible boundary adjustments as well as other enrollment management strategies (e.g., adding portables). One of the major objectives in planning new schools and creating attendance areas is to plan an expansion that involves the least disruption of students and school reassignments (Lemberg and Church, 2000). In a different example, to meet the fluctuations in daily emergency '911' call demand in San Diego County, CA, Rural Metro Medical Response operates between 2 and 24 ambulances during each day. Posting ambulances at various locations and dispatching them over time is a complicated logistical/spatial optimization problem. Rest assured that the patterns of deployment vary over the day in order to reduce response times, but just where should such posts be located to get the most service out of a limited number of vehicles? Since it costs over US$700 000 per year to keep an ambulance in operation, it is important to find an efficient service plan. As another example, in Los Angeles County, the County, the City of Los Angeles, and numerous other municipalities within the county operate approximately 392 fire stations. Altogether, this system is estimated to cost more than US$2 billion a year to operate. This means that there is an interest in relocating and reducing what is used as well as consolidating services across municipalities, without compromising on service quality, a problem that can be addressed as a spatial optimization problem.

Geographic scale is an equally important issue in spatial optimization. There are typically three basic scales in spatial optimization problems: micro, meso, and macro. The macro-scaled problem involves the highest level or area size (i.e., smallest map scale). At such a level, we might ask: 'in which cities should we have factories or warehouses?' We generally use no specific site information in making such a selection. Interactions between customers and facilities are modeled at an aggregated level. The objective is to identify those areas in which it makes the most sense to open a facility or activity. Such a decision might be considered 'strategic.' If we have a strategic plan to locate a regional warehouse in Reno, Nevada, the 'meso' level question is 'where in Reno should it be?' Such a problem would involve identifying the best available site, considering a wide range of criteria. This is a type of 'tactical'

decision making and is often performed to support a strategic decision. Once we have a site or a place, the micro-scaled problem involves carving up that space and allocating it into specific activities. For example, we may allocate store space to specific retail items or a shop floor to machine tools. Even malls are arranged spatially in order to take advantage of anchor stores and walking patterns (Bean et al., 1988). How people use such facilities and interact with their environment is an especially important aspect of this problem. In the industrial engineering literature, this type of problem is often referred to as a layout problem. Micro-scaled problems are akin to an 'operational level' problem.

Historical Roots of Spatial Optimization

Efficient land use activity was first discussed by Von Thunen in 1842, when he described how agricultural activities including wood lots should be optimally arranged around an isolated village. Primary industries such as forestry now use spatial optimization to identify how each stand (tree type and age class) is to be managed over time. These management plans include the building of roads, the provision of environmental standards, and the return on investment (Church et al., 1998). In Chile, forest companies optimize nearly every feature of their industry, including the scheduling and routing of vehicles for log transport (so that logs arrive when just needed at loading facilities such as ports), the placement of harvest towers and cable ways for steep slope harvesting, and the minimization of land devoted to unproductive elements (e.g., roads). The US Forest Service has utilized a spatial optimization model called FORPLAN (and its successor SPECTRUM) for the last three decades in developing management plans (Kent et al., 1991) for virtually every national forest in the United States.

Alfred Weber proposed one of the earliest industrial location models in 1908 (Wesolowsky, 1993). As a simple example, he described the location of a manufacturing point between two localized raw materials and a market. He considered that the three points could be plotted on a Cartesian plane as shown in Figure 1. Transport distances between the points were assumed to be Euclidean. Weber discussed how, under certain assumptions, that the ideal location was the one that minimized transport costs of the raw materials to the manufacturing point and the product to market. Georg Pick wrote an appendix to Weber's book that demonstrated how this model could be solved geometrically for certain problems. The first optimal solution algorithm for the more generalized Weber model involving many markets and raw materials was developed in 1937 by Weisfeld and reinvented by Kuhn and Kuenne and Cooper as well (Wesolowsky, 1993). Cooper subsequently proposed an extended model involving the location of multiple facilities (Wesolowsky, 1993).

In 1933 Walter Christaller wrote: "if there are now economic laws, then there must be also laws of the geography of settlements" (Christaller, 1966: p. 3). He asks the question: "are there laws which determine the number, sizes, and distribution of towns?" (Christaller, 1966: p. 1). Christaller attempted to find the laws that determined the number, size, and distribution of towns in a region of Southern Germany. Since that time geographers, archaeologists, and anthropologists have searched

Figure 1 The classic Weber location triangle.

for Christaller's central place patterns in other regions and in other applications and have developed spatial optimization models that solve for the optimal spatial arrangement of towns and markets (Kuby, 1989). Virtually all early location theories have some type of spatial optimization counterpart today.

Selected Examples of Spatial Optimization

A large number of spatial design/arrangement/allocation problems have been approached using some form of optimization modeling. Techniques used to solve optimization models are typically found in the operations research (OR) literature. The field of OR traces its roots to World War II and the need to solve large-scale military logistics problems. One of the first OR models that was developed and can be solved optimally was the classical transportation problem. This problem involves a distributed set of supply points (called sources) and a distributed set of demand locations (called sinks). Each source has a finite capacity to supply a good and each destination has a specified amount of demand for that good that needs to be met. Between each unique pair of one source and one sink we can identify the most efficient route and the cost to ship one unit of that good between that source–sink pair. The objective of the classical transportation problem is to allocate the supplies to the demands so that the total transport cost is minimized and so that the demand at each sink is met. Garrison (1959) was the first geographer to discuss the utility of the transportation problem as a model to analyze spatial structure. Yeates (1963) and others have since used this spatial optimization model to analyze efficiency of an existing arrangement or to develop an optimal transportation plan.

Table 1 gives a representative sample of spatial optimization problems that can be found in the literature, including the classical transportation problem. The list includes vehicle

Table 1 Examples of spatial optimization problems

Problem name	*Problem definition*	*General reference*
Corridor location problem	Across a landscape, identify the optimal route for a right-of-way for a facility such as a pipeline, highway, or power transmission line that connects an origin and destination; across a landscape identify an efficient corridor for wildlife movement between two habitat cores.	Lombard and Church, 1993; Kemp and O'Hanley, 2010
Vehicle routing problem	Optimally route a vehicle from a starting point to visit a number of prespecified locations and then return to the starting point.	Weigel and Cao, 1999; Thill et al., 2011
Classical transportation problem	Allocate limited supplies at different locations to a number of spatially distributed demand points in such a manner as to minimize transportation costs of serving all demand.	Yeates, 1963; Camm et al., 1997
Simple and capacitated plant location problems	Locate a set of facilities and allocate their supplies to demand points in such a manner as to minimize facility and transportation costs.	Upchurch et al., 2009; Kuby et al., 2011
p-median location problem	Locate *p*-facilities so that the total weighted distance of serving all demand is minimized.	ReVelle and Swain, 1970; Densham and Rushton, 1992
Maximal covering location problem	Locate *p*-facilities so that the largest proportion of demand is covered or served within some maximal distance or time	Church and ReVelle, 1974; Tong et al., 2009
p-hub location problem	Locate *p*-transportation hubs and allocate demand to specific hubs in such a manner as to minimize total transportation costs.	O'Kelly and Miller, 1994
Site configuration/design problem	Identify the best set of parcels or land units that optimizes costs and meets shape, contiguity, size, and suitability constraints	Wright et al., 1983; Williams 2002
Districting, zonation, and region delineation problems	Partition spatial units into a set of districts or regions that optimize one or more criteria, examples school districts, political districts, etc.	Openshaw, 1997; Duque et al., 2012
Spatial allocation problem	Allocate specific activities to defined spatial units	Aerts et al., 2003; Ligmann-Zielinska et al., 2008
Disruption, fortification, and resilient design	Interdict a system in a manner to inflict the most harm, protect a system so that it escapes the most harm, design a system which is resilient to natural or artificial disasters	Grubesic et al., 2008; Church et al., 2004

routing, districting and zonation, transportation, facility location, site search, and space allocation. For each of the 11 problems listed, the name, definition, and a few references are given. For each of these generic problems, a number of models have been developed. The references cite the original work, a review, or a recent work that contains an up-to-date list of references. All but the last problem listed are classic problems that have been the subject of numerous papers in the geographic and regional science literature. The last problem area is relatively new and addresses issues of disruption, fortification, and resilience. Although there are classic spatial problems of risk such as delineating a flood plain or modeling a plume from a hazardous chemical spill, recent attention has been directed at the potential for system disruption and failure. Since the attack on the New York World Trade Center in 2001, concern for disruption, designing for resilience, and managing disasters have become a major research area. For example, Grubesic and Murray, (2006) examined the Internet backbone with the intent on finding those nodes which when removed would cause the greatest disruption to network topology (Grubesic et al., 2008). Church et al. (2004) developed an interdiction model to find those facilities of a system that are critical to efficient operation. It is logical to ask, how should protection resources be allocated to prevent disastrous outcomes (Church and Scaparra, 2007) and how can failures cascade through numerous interconnections and networks (Grubesic et al., 2008). Finally, shelter locations, evacuation routes, and resources for emergency services for making a quick response during hurricanes and other natural disasters have become an important area addressed by those working on spatial optimization problems (Alçada-Almeida et al., 2009).

All of the problems listed in **Table 1**, with the exception of the corridor location problem and the classical transportation problem, have a problem complexity that is called *Nondeterministic Polynomial* (*NP*). The class *NP* refers to a set of problems for which there exists virtually no chance that procedures will be found that can solve all problems optimally within a reasonable computational time on a computer. One of the reasons for this is that these problems require the use of integer programming, an area of optimization that can be both computationally intensive and limited in terms of the size of an individual application that can be solved optimally. Because of this fact, it is common to see that different techniques are used for solving specific models and that heuristics are needed for most moderate to large sized problems (see, e.g., Tong et al., 2009). Heuristics are specialized solution procedures that are designed to approach problem solving using either a set of rules or some search strategy. An example of a heuristic is given in the next section.

A Detailed View of a Spatial Optimization Problem

Hakimi (1965) proposed a network location model called the *p*-median problem. Consider the network depicted in **Figure 2**. Each node is connected to other nodes by arcs of given distances. Without any loss of generality, consider that each node represents a potential facility site as well as a point of demand. The measure of demand is represented as a demand

Figure 2 An example road network.

weight (in units of people, tons, trips, or some other measure of need to be supplied by a facility). Assume that each demand will be supplied or served by the closest facility. The transportation cost is assumed to be directly proportional to the weight of a demand multiplied by the distance to the closest facility (note: this is the same assumption used in the Weber model). The p-median problem involves selecting the locations of p-facilities so that the total weighted distance for all demand is minimized. Hakimi proved that at least one optimal solution to the p-median problem consists entirely of nodes of the network. Thus, the search for an optimal configuration can be limited to just the nodes of the network.

Searching for the best nodal configuration, and hence an optimal configuration, seems simple. Why not enumerate all of the possible facility patterns, and pick the configuration with the lowest weighted distance? Unfortunately, it is not that simple. Consider for example that we wish to locate 10 facilities on a network of 100 nodes. Such an enumeration would involve generating and evaluating the following number of combinations:

$$\binom{100}{10} = \frac{100!}{5!(100-5)!} = \frac{100*99*98*97*96*95*94*\ldots*1}{10*9*8*\ldots*1*90*89*88*\ldots*1}$$

or

$$\frac{100*99*98*97*96\ldots*91}{10*9*8*7*\ldots*1} \cong 17\,300\,000\,000\,000 \quad \text{configurations or alternatives.}$$

If a very fast computer could analyze 1000 solutions each second, it would take 548 such computers working simultaneously to finish the task in a year. Thus, for many problems enumeration is impossible. Since enumeration is not possible for many problems, it is reasonable to consider optimization. ReVelle and Swain (1970) proposed the first optimal approach to solving the p-median problem. The basis of their approach is to formulate the p-median model as an integer programming problem.

Consider a connected transportation network comprised of n nodes and at least $n-1$ arcs (note: it requires at least $n-1$ arcs to be connected). An example of a 12-node network is given in Figure 2. In this review we will consider the most general form of the p-median problem where each node represents both a place of demand and a potential facility site. Given any pair of nodes on the network, a shortest path exists between the pair of nodes, and the distance of that path is easily calculated by a variety of efficient techniques. Consider the following notation:

n = the number of nodes in the network
i,j = indices used to reference nodes, where the nodes are numbered from 1 to n
a_i = the amount of demand at node i
d_{ij} = the distance from node i to node j

$$x_{ij} = \begin{cases} 1, & \text{if demand at node } i \text{ assigns to a facility at node } j \\ 0, & \text{otherwise} \end{cases}$$

$$x_{jj} = \begin{cases} 1, & \text{if node } j \text{ self assigns indicating that a facility is located at node } j \\ 0, & \text{otherwise} \end{cases}$$

Using the above notation, we can define the following optimization model (ReVelle and Swain, 1970):

Objective function:	Minimize $\sum_{i=1}^{n}\sum_{j=1}^{n} a_i d_{ij} x_{ij}$	
Subject to:		
1. Each demand must be served by either placing a facility at its node or by assigning to a facility elsewhere	$\sum_{j=1}^{n} x_{ij} = 1$	For each node i
2. Assignment is possible to only open facilities, where demand self-assigns	$x_{ij} \le x_{jj}$	For each node i and j where $i \neq j$
3. Exactly p-facilities are located	$\sum_{j=1}^{n} x_{jj} = p$	
4. Integer restrictions on variables	$x_{ij} = 0,1$	For each node i and j where $i \neq j$

The above model can be solved by the use of integer programming techniques, most notably, linear programming with branch and bound (LP/BB). In a relatively high percentage of problems, the optimal linear programming solution is integer optimal as well and the BB routine is not used. This property is called 'integer friendly.' Since BB algorithms may take considerable computational time to resolve noninteger solutions, finding an optimal integer optima without BB usually means relatively fast computational times for a given problem size. Unfortunately, the above model is large in terms of the number or variables and constraints (n^2 and n^2+1 respectively). Consequently there is a limit as to how large a problem can be solved by this specific model formulation and LP/BB.

It is possible to formulate the p-median problem with a slightly different constraint set. Consider the following form of the second constraint:

2. Assignments are possible to a facility, only if it has been selected	$\sum_{i=1}^{n} x_{ij} \leq (n-p)x_{jj}$	For each node j

The constraints that restrict demand assignments to only those nodes selected for a facility have been aggregated into one constraint for each facility. Consequently, this second model is more compact in that it contains only $2n + 1$ constraints rather than $n^2 + 1$ constraints. As models are typically easier to solve when they have fewer constraints, this would at first seem to be an improvement. Unfortunately, this second model form is not 'integer friendly' and consequently the use of LP/BB typically relies on the BB algorithm and resulting solution times can be very large. The lesson here is that there are always alternate ways in which to formulate any given spatial optimization model, and the difficulty in solving a given problem can be in part due to the mathematical form of the problem. The original problem formulation has met the test of time, as it is still the formulation of choice in describing the p-median problem. There are, however, new attempts at reformulating this problem so that it uses as few variables and constraints as possible. These models are particularly tuned to spatial properties (Church, 2008).

There are practical limits, however, as to the size of a p-median problem that can be solved optimally. For very large problems it is simply not possible to find an optimal solution with certainty. Because of this there has been a great reliance on heuristic solution procedures. Heuristics are often designed to exploit some type of search strategy. For example one of the best-known methods for solving the p-median problem is the 'swap' heuristic of Teitz and Bart (Densham and Rushton, 1992). The 'swap' heuristic starts with a randomly generated solution. Given this starting solution, each node is considered in turn as a possible replacement site for each of the currently selected nodes. If any swap involving this candidate node yields an improvement, the best swap with that candidate is made, creating a new and improved solution. Swaps are tested until no improvements can be made involving any node of the network. Repeating this procedure a few times has a good chance of finding a good, if not optimal solution. Other strategies are based upon 'survival of the fittest' genetic algorithms, simulated annealing and statistical mechanics, Tabu search, Monte Carlo sampling, etc. All heuristics are rated for their capabilities in finding good solutions.

The Problem of Aggregation and Domain Representation

Virtually all spatial problem representations contain some type of abstraction. For instance, it is impossible to completely characterize all elements of a coastal boundary without some form of line generalization. In the p-median problem described above, demand locations and possible facility locations were restricted to the nodes of a network. The basic problem in applying a spatial optimization model, like the p-median model, is in defining the scale at which sites and demand points are represented. For example, would one define each household as a demand point and vacant buildings and lots as potential facility locations or sites? Or, would it be more appropriate to aggregate demand to census blocks, census tracts, or some other spatial unit? The problem is that aggregation for spatial analysis and optimization, in and of itself, introduces the possibility of error, which was first recognized by Goodchild (1979). Goodchild described the problem of aggregating demand points into zones for the purpose of applying a location-allocation model and demonstrated that spatial differences in the final solution can be attributed to the process of problem aggregation.

The other issue of major importance is problem domain representation. Spatial optimization problems have been cast on continuous domains and discrete domains. For example, the p-median problem defined in the previous section was defined for a discrete domain of demand points and facility sites. However, the related Weber problem depicted in **Figure 1** is defined on a continuous Cartesian coordinate system where any point is a feasible facility site. Both continuous and discrete domains have their own attendant problems. One problem that has received considerable attention is the location of warning sirens across a bounded region, so that all points within the region are within a specified distance of a siren, where the objective is to minimize the number of sirens needed to cover the bounded region. In this case, the demand is described as a bounded polygonal region and the sites are defined as any point within the region (Tong and Murray, 2012). Whereas some problems are more easily approached as a discrete optimization, their counterpart continuous spatial representation may represent a more realistic application domain. Unfortunately, most discrete domain problems, although computationally difficult in themselves are more computationally tractable than their continuous domain counterparts.

Research Needs in Spatial Optimization

Research in spatial optimization has expanded over the years. This expansion is due in part to increasing computational power and availability of computers, better general purpose commercial products like Geographical Information Systems (GIS) and optimization software, fourth generation computer language tools like visual studio and C++, and high resolution displays. Some spatial optimization models are now a part of general purpose GIS software. There are, however, a number of research directions that must be taken in order for such modeling tools to be commonly available. To make this a reality, research is needed in the following areas:

1. develop better and more capable solution algorithms and heuristics. This is especially important in improving the capability to solve large problems of the simple plant location problem where the facilities have finite capacities;
2. expand existing models and develop more comprehensive spatial optimization models, especially in ecological reserve design and land use planning;
3. develop methods to better estimate the impact of data error and its propagation on model results. This is especially

important since all geographic data sets of realistic size contain error;

4. expand data model definitions and problem representations to better link spatial optimization models with GIS. See Tong and Murray (2012) for a good description of some of the nuances of spatial representations and model definitions. One application of considerable importance is the optimal location of cellular phone towers;
5. develop better visualization methods along with graphical interface approaches that can support collaborative decision making processes;
6. explore methods of data aggregation so that it may be possible to construct small problem representations that are easier to solve, but still retain all of the important problem characteristics.

Many industries and government agencies have been pushed to become more efficient. Increasing productivity has become a mantra of stockholder and citizen alike. In many settings new spatial optimization models are being proposed to help increase efficiency, promote equity, reduce environmental damages, and reduce energy needs (see, e.g., a carbon capture and sequester model by Kuby et al., 2011). For example, new spatial/temporal optimization models that are being used for emergency ambulance operations can create plans that improve service response without additional investment or keep service levels constant and cut costs. The economic incentive to improve services and reduce costs will expand the application base that is already very large.

Abstract

Spatial pattern analysis methods provide insights about where things occur, how the distribution of incidents or the arrangement of data aligns with other features in the landscape, and what the patterns may reveal about potential connections and correlations. Focusing primarily on vector data (points, lines, and areas), this article introduces a sampling of descriptive and inferential exploratory spatial pattern analysis methods relevant to a variety of real-world problems and questions. Web links to additional resources for learning more about spatial pattern analysis are included in tables at the end of the article.

Spatial pattern analysis involves identifying, describing, and measuring the shape, arrangement, location, configuration, trend, or relationships in geographic data. Data are spatial or *geographic data* when they are collected with, or assigned, locations such as an X and Y coordinates (longitude and latitude) or an address. When data are associated with locations, they can be mapped, and mapping geographic data is an important first step in analyzing spatial patterns.

The next steps involve identifying, describing, and measuring the spatial characteristics of data. Is there a discernible pattern, order, or structure associated with a disease outbreak, a series of public protests, the results of state-wide test scores, or emergency call events? Researchers and analysts look for spatial patterns in data because often understanding *where* things occur provides important clues about *why* things occur. Understanding why (i.e., cause–effect relationships) has been described as the 'holy grail' of science (Cressie and Wikle, 2011), because it offers the potential for changing outcomes: remediation, intervention, alteration. When you understand the patterns associated with a series of crime events, for example, you have an important tool for predicting future crimes. Examining the patterns associated with consumer behavior can help focus marketing efforts to increase sales. Analyzing spatial variations in childhood obesity can help inform policies and programs aimed at reducing this growing epidemic.

Sometimes looking at a map is all that is required to identify and explain spatial patterns. It is important to recognize, however, that the cartographic decisions made when a map is created can have a big impact on what a map communicates (Monmonier, 1996). The maps below (**Figure 1**), for example, show standardized health care costs by hospital regions in the contiguous United States. All three maps are based on the same underlying data; the only difference is the cartographic display (class breaks based on equal intervals, quantiles, or standard deviations).

Consequently, when visual analysis is not sufficient to identify or to explain spatial patterns or when you need to quantify or to make inferences about the patterns in spatial data, you will want to adopt a more formal analytical approach. Focusing primarily on vector data (points, lines, and areas), this article presents a small sampling of the many spatial pattern analysis methods that can be used to move beyond visual analytics in order to describe, quantify, and effectively map spatial patterns. The first section covers simple descriptive pattern analysis methods. The second and third sections describe inferential methods for quantifying and mapping spatial patterns. The article concludes with some comments on future directions and links to web pages with more details, the math behind the methods, and the resources for learning more.

Describing Spatial Patterns

Descriptive spatial pattern analysis methods summarize the key characteristics and properties for a set of geographic features and their associated attribute values. **Table 1** provides examples of some geographic features, how they might be represented on a map, and potential attributes.

If asked to analyze a set of numbers such as household incomes, one might begin by computing the mean and the standard deviation. Similarly, analyzing spatial data often begins with computing spatial versions of the same statistics: the mean center and the standard deviational ellipse. Calculating the mean center helps understanding the central tendency of the features, and calculating the standard deviational ellipse highlights the spatial distribution and orientation of features around the mean center. Using these descriptive pattern analysis methods to summarize important spatial properties in data is an effective strategy for comparing groups of features across space (e.g., race/ethnicity integration or segregation) or highlighting changes in spatial patterns over time (e.g., urbanization trends).

Central Tendency

Points and Areas

Measures of central tendency are simple descriptive statistics that can help answer questions such as:

- Which resource is most accessible?
- Has the center of innovation changed over time?
- What is the primary direction of migration?

The most common measure of central tendency is the mean center statistic. It is computed as the average X coordinate and

Figure 1 Geographic variations in per capita health care costs for Medicare recipients by hospital referral region, 2010. Data source: http://www.iom.edu/Activities/HealthServices/GeographicVariation/Data-Resources.aspx.

the average Y coordinate for all features in a data set. Although it is a simple statistic, it has powerful applications. Epidemiologists, for example, might compute the mean center for a set of health events in order to gather clues about the potential sources of a disease or to better understand mechanisms of disease transmission (Koch, 2005).

When the mean center is calculated using an attribute value as a weight, the effect is to pull the mean center toward the features with the largest attributes. A retail analyst looking for potential warehouse locations to serve a chain of grocery stores, for example, might compute a weighted mean center using the sales volume attribute for each store. By including this attribute in the mean center calculation, the X and Y coordinates for stores with the largest sales volumes will have the strongest impact on the resulting location of the weighted mean center (Mitchell, 2005).

In **Figure 2**, the weighted mean center for the population of California has been computed each decade between 1900 and 2000. In the first part of the century, the mean center is near San Francisco, perhaps reflecting the maritime trade and earlier population booms associated with the 1848 discovery of gold in the region. With each decade, however, the weighted mean center moves south owing to stronger population growth in southern California. This southern-moving trend is likely a reflection of the economic opportunities associated with the burgeoning movie and oil industries, as well as the increasing availability of air-conditioning (Scott and Janikas, 2010).

Lines

For line features, central tendency is computed using a circular statistic to summarize either the mean direction or the mean orientation. Given a set of lines representing animal movements, for example, calculating the mean direction will distinguish between the spring and fall migration pathways. Alternatively, calculating the mean orientation for data spanning all four seasons would be appropriate if the main focus is identifying the key corridors that migrating animals use. While a mean direction is often expressed as a line with one arrowhead, the mean orientation is general represented by a line with two arrowheads (**Figure 3**).

Other measures summarizing line features include the mean line length, mean center point, and circular variance. The *circular variance* is analogous to a standard deviation. It ranges from 0 to 1 and indicates how similar or how different the angles for a set of lines are from each other. Consider an analysis of lines at locations throughout southern Australia representing primary wind directions in January. If everywhere in the study area the wind blows consistently to the northeast, the circular variance will be near 0. If, on the other hand, the wind direction changes drastically from one location to the next so that it blows in many different directions depending on location within the study area, the circular variance will be near 1.

Applications for mean orientation include analyzing roads, urban spatial structure, or fault lines (Mardia and Jupp, 2000; Gaile and Burt, 1980). Mean direction applications include analyzing the consistency of hurricane pathways, migration routes for animals or people, or regional wind patterns. Mean direction has been used to analyze geographic variations in journey to work (Corcoran et al., 2009), to model journey to crime (Van Patten and Delhauer, 2007), and, more broadly, to describe patterns of transport, spatial interaction, flows, or diffusion (Gaile and Burt, 1980).

Spatial Distribution

While the mean center and linear mean pattern analysis methods provide information about central tendency,

Table 1 Examples of spatial features, geometric representation, and feature attributes

Features	*Typical geometry*	*Example attributes*
Cities	Points representing the center of a city or areas representing city boundaries	Unemployment rate, jobs, Hispanic population
Traffic accidents	Points	Severity, fatalities, date, time
Roads	Lines	Speed limit, traffic volume, road condition
Parks	Areas or points	Acreage, entry fee, estimated annual visitors
Counties	Areas	Population, average home values, median incomes

Figure 2 The center of population moves steadily south between 1900 and 2000 as growth in southern California outpaces population growth in northern California. Adapted with permission from Scott, Lauren M., Janikas, Mark V., 2010. Spatial statistics in ArcGIS. In: Fischer, M.M., Getis, A. (Eds.), Handbook of Applied Spatial Analysis: Software Tools, Methods and Applications. Springer-Verlag, Berlin. Data source: http://www.census.gov/population/cencounts/ca190090.txt.

descriptive spatial statistics like the standard deviational ellipse summarize the distribution and orientation of features around the mean center. These pattern analysis tools help answer questions like:

- How quickly and widely is a disease spreading through the village?
- Where are the core areas for particular language dialects? How integrated are they and which have the broadest spatial extent?

Figure 4 shows an analysis of gang territories based on graffiti locations for cases where the gangs responsible could be identified. Each color reflects a different gang affiliation. Creating a standard deviational ellipse for each set of these gang-related incidents provides information about the core extent of gang territories and how the territories relate to each other and to various features in the landscape. Further, areas where the ellipses overlap are a good indication of locations with higher risk for gang-related conflict. This type of spatial pattern analysis can be very useful for making decisions about how best to allocate scarce police resources.

The size of the ellipse created is a function of the standard deviation of both the X and the Y feature coordinates, rotated to minimize the distance between the points and the axes of the ellipse. Analytics using standard deviational ellipses include creating a spatial index of segregation (Wong, 1999), targeting resource distribution for disease control (Eryando et al., 2012), and predicting crime (Kent and Leitner, 2007; Levine, 2002).

Figure 3 The linear mean statistic can assess overall direction or orientation.

Quantifying Spatial Patterns

Beyond the simple descriptive pattern analysis methods, a number of inferential statistical tests can effectively quantify

Figure 4 Standard deviational ellipses used to identify core gang territories. Adapted with permission from Scott, Lauren M., Janikas, Mark V., 2010. Spatial statistics in ArcGIS. In: Fischer, M.M., Getis, A. (Eds.), Handbook of Applied Spatial Analysis: Software Tools, Methods and Applications. Springer-Verlag, Berlin. Data source: simulated based on expert knowledge.

spatial patterns. These methods compare the observed pattern of features, or feature attributes, against a theoretical spatial pattern. Most often, the theoretical pattern used as a baseline is complete spatial randomness (CSR) and, consequently, the null hypothesis for these statistical tests is that the observed pattern is the result of underlying spatial processes that are random in nature. These methods calculate the probability, expressed as a *p*-value, that the null hypothesis is correct. A small *p*-value (<0.05 or, more conservatively, <0.01) indicates statistically significant spatial patterns in the data, providing evidence that nonrandom spatial processes are at work. Only nonrandom spatial processes suggest cause–effect relationships and, consequently, indicate possible opportunities for remediation or intervention.

In addition to calculating *p*-values, these tools often report corresponding z-scores to indicate how the observed spatial patterns deviate from CSR. Spatial patterns that are statistically significant because they are more clustered than CSR generally reflect infectious, transmittable, or attracting types of underlying local spatial processes. For example, it is not uncommon for the retail, financial, and industrial activities in a city to cluster the result of zoning ordinances and/or to take advantage of economies of scale or economies of agglomeration. Spatial patterns that are statistically significant because they are more dispersed than CSR generally result from some form of competitive process where features repel each other in order to create distance. Only small trees can grow under big trees, for example. The small trees will be clustered as a result of seed transmission processes but will thin out over time, the result of competition for local resources.

A number of inferential pattern analysis methods focus specifically on the spatial pattern of point features. A common, decades-old method widely used in geography and ecology is the average nearest neighbor statistic. It works by computing the mean distance to each feature's closest neighbor and then comparing that distance to the distance that would be obtained for a random distribution of those same features (Mitchell, 2005). Another method, quadrat analysis, overlays point features with a fishnet mesh and counts the number of points occurring within each quadrat. A chi-square statistic is then used to assess how likely it is that the observed distribution of points among the quadrats might be the result of random spatial processes (Burt et al., 2009). Kernel density techniques extend the quadrat method by considering point intensity within a predefined radius, generally presenting results as a map-based surface (Murray, 2010). The K function is unique in that it looks at spatial clustering and dispersion for a range of distances, providing clues about the spatial scales at which the processes promoting clustering or dispersion are operating (Scott and Janikas, 2010; Csillag and Boots, 2005). These point pattern analysis methods can help answer questions like:

- Which types of businesses are most concentrated?
- Does the spatial pattern of a disease mirror the spatial pattern of the population at risk?

More common in the social and behavioral sciences are measures that consider both location and feature attributes. These methods typically operate on area features such as census tracts, parcels, or cities, where data have been aggregated to represent counts or rates. They provide a single summary statistic that quantifies *spatial autocorrelation* or the degree to which features nearby in space are similar with regard to a measured attribute (Getis, 2010). Consequently, global measures of spatial autocorrelation such as the Moran's I statistic are especially effective for understanding broad spatial patterns and trends (Mitchell, 2005). They can help answer questions like:

- Is there an unexpected spike in the number of riots or public protests?
- Is the new virus remaining geographically fixed or is it spreading to surrounding communities?

The thematic maps below (**Figure 5**) illustrate relative per capita income, by county, for the state of New York over several years. The darker areas reflect higher incomes. Unfortunately, a visual inspection of these maps is not sufficient to determine whether spatial segregation among the rich and poor counties is increasing or decreasing. It is difficult to discern the answer because doing so requires visual detection of both global and local differences among multiple locations over several years. Using the global Moran's I tool to quantify the degree of clustering for each year, however, and then creating a line graph of the z-score results, makes the overall trend clear (**Figure 5**). A higher z-score reflects more intense clustering. Consequently, the resulting sinking line of the z-score graph indicates that clustering is dissipating. This pattern analysis provides some evidence that spatial segregation among the New York counties has decreased overall between 1969 and 2002 (Scott and Janikas, 2010).

Similar to the K function, the global Moran's I statistic can be used to assess clustering across multiple spatial scales. By running the global Moran's I statistic for increasing distances and plotting the resultant z-scores, a picture of spatial autocorrelation emerges (**Figure 6**). Peak z-scores indicate distances where the processes promoting spatial clustering are most pronounced, and these distances often serve as appropriate scales of analysis for the local spatial autocorrelation methods discussed next.

Mapping Spatial Patterns

Global spatial autocorrelation measures, like the Moran's I statistic discussed in the previous section, help to quantify broad trends in data by computing a single indicator to summarize the statistical likelihood that the observed data reflect a random spatial pattern. They answer the question: is there a discernible spatial pattern or not? For geographic analyses, however, the more interesting question is often: where are the statistically significant spatial patterns located? Where are the hot spots, cold spots, and spatial anomalies? To address questions like these, local versions of the global spatial autocorrelation statistics, such as the Getis-Ord Gi* and the Anselin Local Moran's I, have been developed (Anselin, 1995; Ord and Getis, 1995; Getis, 2010). These pattern analysis methods consider each feature within the context of nearby neighboring features and compare local statistical properties of an attribute to global properties. If the local mean for a feature and its neighbors is unexpectedly large compared to

Figure 5 Relative per capita incomes by county for New York. Adapted with permission from Scott, Lauren M., Janikas, Mark V., 2010. Spatial statistics in ArcGIS. In: Fischer, M.M., Getis, A. (Eds.), Handbook of Applied Spatial Analysis: Software Tools, Methods and Applications. Springer-Verlag, Berlin. Data source: Bureau of Economic Analysis, www.bea.gov/regional/.

the global mean (i.e., the mean value for all features in the data set), it is indicative of a *hot spot* (a spatial cluster of high values). Similarly, an unexpectedly small local mean suggests a *cold spot* (a spatial cluster of small values). An individual feature with a large attribute value surrounded by features with small values, or a feature with a small value surrounded by features with large values, reflects spatial anomalies. Accounting for the number of features and global variation in the attribute value being analyzed, these methods determine if the differences between the local and global properties are statistically significant, and return a result (a *p*-value and/or z-score) for every feature in the data set. Mapping these results effectively illustrates the spatial patterns (Aldstadt, 2010).

Local spatial autocorrelation statistics are used in a number of application areas including crime (Ratcliffe, 2010; Scott and Warmerdam, 2005) and health (Haque et al., 2012; Getis, 2004). In **Figure 7**, the Anselin Local Moran's I statistic is applied to data from the 2008 United States presidential election. The map shows statistically significant clusters of the Republican and the Democratic political party victories as well as spatial anomalies. A political strategist could use the results from this type of pattern analysis to help design more effective canvassing. Active campaigning in counties without strong allegiances to either party may be more effective than investing campaign money in counties where the opposing party has had strong wins. The spatial outlier (**Figure 7**) in the southern part of Texas reflects a Republican Party win surrounded by counties strongly supporting the Democratic Party. Understanding what makes the political leanings in this county so different from

Figure 6 Analyzing the spatial pattern of crime, the peak z-scores at 3500 and 5500 feet reflect distances where the processes promoting clustering are most pronounced. Analysis is based on data obtained from https://data.cityofchicago.org/.

its neighbors may help strategists design targeted messaging to win votes there.

Another approach to cluster analysis identifies groups of features based on inherent similarities for a set of specified attributes. The most commonly used methods rely on K-Means algorithms, but a number of other methods have also been developed (Murray, 2010; Duque et al., 2007), including methods that impose both spatial and temporal constraints on group membership (Esri, 2012). The goal of these methods is to classify features into natural groupings such that both the within-group similarity and the between-group differences are maximized. These methods have been used to study regional economics (Duque et al., 2006) and have been proposed for analyzing cancer rates (Guo and Wang, 2011). While these methods have been used most often in the physical sciences (e.g., climate zoning, landscape analysis) and for image classification, they have much broader application whenever there is a need to create homogeneous regions or to elucidate hidden patterns in spatial data (Miller, 2009; Guo and Wang, 2011). With increased availability of high-resolution spatial data, these types of analytics will be needed for understanding human–environment interactions and socioeconomic dynamics, and to address critical problems such as global climate change (Guo and Mennis, 2009).

Future Directions

Looking into the future of spatial pattern analysis methods and applications is both exciting and overwhelming. According to IBM (Selinger, 2013), 90% of the data today has been generated in the past 2 years, and new data are being created more quickly than are algorithms capable of processing them. Sources of these data include purchase transactions, sensors monitoring climate, and other aspects of the physical world, vehicle electronic transmissions (cars, planes, and ships, for example), utility meter readings, a host of data generated from social media sources (e.g., digital photographs, videos, blogs, tweets), and Global Positioning System-enabled mobile devices (Selinger, 2013). As a consequence, the ability to effectively describe, quantify, and map spatial patterns is becoming more important than ever. The challenge is not only dealing with this large volume of messy, dynamic, streaming data but also effectively analyzing its multidimensional characteristics.

Even prior to analytical considerations, however, methods for filtering data to eliminate noise, detect and remove errors, reduce redundancy, compensate for missing data, and deal with uncertainty will need to be refined. These filtering methods are a precursor to powerful analytics that must be capable of detecting and then predicting unexpected patterns, correlations, and trends. Effective pattern analysis techniques are not yet well developed for dealing with space, time, and mobility simultaneously. Methods that can detect coevolving spatial–temporal patterns – various event series that have similar tracks (similar spatial–temporal 'fingerprints') based on mutual locations, social networks, behaviors, opportunities and histories – also need to be developed (Shekhar et al., 2009).

Once these new pattern analysis methods are implemented, however, additional challenges surround how best to communicate the multidimensional results. An important goal

will be to extend descriptive cartographic visualizations (such as animations) by developing mathematical and statistical frameworks. These will be required to detect, for example, significant trends or anomalies from the increasing information overload in order to motivate effective action (Murray, 2010). In summary, development of new spatial pattern analysis methods, algorithms, and applications represents vital areas of research where scholars and analysts in the social and behavioral sciences can make enormous contributions.

Spatial Sampling

Robert Haining, Human Geography, University of Cambridge, Cambridge, UK

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Spatial sampling is undertaken to estimate an attribute of a spatially distributed population. The attribute might relate to a quantity (how much) or to the distribution of values (where). Two models underlie spatial sampling, the design-based and model-based approaches, and these are described. A key issue with spatial sampling is selection of the sample sites. We describe random, stratified random, and systematic spatial sampling and comment on their properties. Other forms of sampling, including clustered and nested sampling as well as progressive sampling including spatially adaptive sampling, are described. We discuss the implications of spatial heterogeneity and spatial autocorrelation for spatial sampling.

Sampling is undertaken in order to estimate one or more attributes of a population. Sampling is used instead of undertaking a census for many reasons. For example, a census may be impossible because the population is very large, perhaps even infinitely large, or it may be impractical because of cost. Some UK census data are made available only as a 10% sample partly to help preserve confidentiality but also because the data require manual coding, which is expensive. A census may be unnecessary because a value for the attribute is only required up to some predetermined level of precision and a sample size and estimator can be specified that will achieve the required level of precision. Sampling is also undertaken to improve the accuracy of databases because some methods of recording are known to produce undercounts (e.g., in the case of crimes, not all events are reported to the police) and some methods of enumeration miss certain groups in the population (e.g., the homeless in the case of a national census).

The term 'spatial sampling' is used to describe the activity of sampling when the population is spatially or geographically distributed. All of the individuals in the population have a geo-reference or geo-code that identifies their location with respect to some local or global frame of reference. The population might be a surface of land-use values or ground-level air pollution. In this case the population is the set of all points in the region and is infinitely large. The population might be the set of all households in a city, in which case the population, while not infinite, is nonetheless very large. The population might refer to spatial aggregates. For example, the population of households might be bundled into census units, so that the population is the set of such units for which aggregate quantities are of interest.

Spatial sampling is usually undertaken by recording data values at point locations such as positions on a line or surface, or recording some aggregate quantity for polygons (e.g., pixels, quadrats, or census tracts). In household sampling, a household may be treated as a point (is the head of a household unemployed?) or as an area-based quantity (number of persons per room).

Spatial sampling to estimate a population attribute involves (1) selecting the sample size (n); (2) specifying the sample locations ($s_1,\ldots,s_n$) according to some set of rules, often called the sampling plan; (3) choosing an estimator (for the population attribute); and (4) calculating the sampling error of the estimate. The sampled data $\boldsymbol{z} = \{z(s_1),\ldots,z(s_n)\}$ are used to estimate the attribute, which might be a 'nonspatial' attribute such as the mean value of the variable Z, or the proportion of the population with a given set of values on Z, or the maximum value of Z. These are sometimes referred to as 'how much' questions. The attribute to be estimated might be 'spatial': estimating the autocorrelation or semivariogram structure of the population, obtaining a map of the attribute of interest, or locating extreme or rare events. These are sometimes referred to as 'where' questions. In each case it is necessary to choose an appropriate estimator of the quantity and calculate the sampling error of the estimate.

There may be other issues that affect spatial sampling. There may be, for reasons associated with cost, a trade-off between on the one hand the greater levels of precision (smaller sampling error) obtainable by increasing the sample size versus the costs associated with collecting larger volumes of data. A sample survey that delivers acceptable levels of sampling error for a national survey will not achieve equivalent levels at smaller state or county-level scales without a larger sample and without stratification (by state or county). Hence there needs to be some assessment of the benefits of having information at the smaller scale set against the costs of a larger sample. One solution to this problem, which can be used where an estimate is available at the local level, is to adapt methods based on 'borrowing strength.' National surveys yield precise estimates of national rates, but these are biased estimators of local area rates because local areas have different rates. Estimators of local rates may be unbiased but because of small sample size (if many areas need to be surveyed) they are likely to have low precision. Estimators that 'borrow strength' combine these two sources of information by using weights that reflect the relative precision of the two estimators (Ghosh and Rao, 1994; Longford, 1999). Instead of borrowing strength from the national estimate, information can be borrowed just from geographically adjacent regions, a practice used, for example, in small-area disease-rate mapping (Elliott et al., 1992; Rao, 2005).

There may be particular problems of access to particular sample areas as well as the collection costs associated with adopting a dispersed distribution of sampling locations versus a more clustered distribution. Other issues may also need to be considered, such as whether sampling is required to undertake long-term monitoring and whether there are to be several

measured attributes recorded at each site so that some compromise is required between the different estimators (Haining, 2003). The form of the sampling problem may be to decide how best to add to, or conversely rationalize an existing sampling network where there may be costs associated with any reconfiguration (Arbia and Lafratta, 1997).

There are situations where some spatial object such as a polygon or a line is to be estimated, in which case the sample design is selected in order to estimate or represent characteristics of the object – such as the area of a polygon or the location of a line. In geographic information system databases, the representation and resolution of boundary lines between polygons is the outcome of a sampling process. The precision with which any boundary or shape can be represented is a function of the spacing of the sample points (Griffith, 1989).

Design- and Model-Based Approaches to Spatial Sampling

Suppose a region R is divided into a population of N units, where N might be very large. In the design-based approach it is assumed that $z(s_i)$ is the value of Z observed at the point s_i, which is one of the N points in R. The value of Z at each of the N units is considered fixed. We let $m(R)$ denote the (unknown) mean of the population of these N values. The problem is to estimate $m(R)$, and in the design-based approach Z is observed at n sample points where these sites have been selected according to some sampling plan where each unit has a known probability of being selected. Repeated sampling according to this scheme generates a distribution of values of the vector $\boldsymbol{z}$. This distribution together with an estimator of $m(R)$ defines a (design-based) sampling strategy. This estimator is used to make inferences about $m(R)$ because, as it is based on $\boldsymbol{z}$, it too will have a distribution of values under repeated sampling.

The model-based approach assumes an underlying random process with an assumed probability distribution that is generating the observed set of values in the N units of R (*see* Spatial Autocorrelation; Spatial Statistical Methods). So the value $z(s_i)$ is the value of a random variable – it is only one of a distribution of values that could have been realized at location s_i. It is usual to specify properties of the model generating the N data values including the first-order (mean, μ) and second-order (variance–covariance, $\sum$) properties. Now $m(R)$ is not a parameter but a random variable because it is a function of N random variables. To make clear the distinction, this mean will be labeled as $M(R)$ in the model-based case. Note that it could also be of interest to estimate parameters such as the mean, μ, of the underlying model.

In the model-based approach, the estimator of μ and the estimator of $M(R)$ both incorporate the spatial model generating the data explicitly in order to produce good estimates (e.g., Haining, 1988; Cressie, 1991). For example, the best linear unbiased predictor of $M(R)$ is of the form:

$$\sum_{i=1}^{n} a(i)z(s_i) \qquad [1]$$

where the $\{a(i)\}$ depend on the model and are chosen to minimize the mean square prediction error. In this approach the sampling plan is of secondary interest.

By contrast, in the design-based approach, the sample mean ($a(i) = 1/n$ in eqn [1]) is used to estimate $m(R)$, having been shown to have good properties (Bellhouse, 1977). Attention focuses now on the sampling plan in order to identify which one will give the smallest sampling variance or sampling error for the estimator. The advantage of this approach is that the estimator is easy to compute and it does not depend on specifying the underlying model. The model-based approach assumes a hypothetical superpopulation of possible (but unrealized) maps. The design-based approach is only concerned with the here and now of what has occurred. Perhaps more importantly from a conceptual perspective, the model-based approach can be used to estimate the parameters of the underlying signal (the parameters of the map generator, such as μ) rather than the particular (noisy) map. For example, in relative risk estimation (e.g., disease mapping), it is a quantity such as μ (the underlying mean relative risk) rather than $M(R)$ that is usually of interest (Elliott et al., 1992).

For a fuller discussion of the distinctions discussed in this section, see Brus and deGruijter (1997).

Sampling Plans

There are a number of different ways to select the sites to be sampled, and choice depends on the purpose of the sample and (possibly) the resources available for carrying out the survey. We first discuss random, stratified random, and systematic spatial sampling (Ripley, 1981) before turning to look at other sampling plans.

In the case of random sampling, the n sample sites are selected so that each member of the population has an equal and independent chance of selection. **Figure 1(a)** shows a random sampling plan on a surface where each point on the surface had an equal chance of being selected. **Figure 1(b)** shows a stratified random sampling plan on the same surface that has been divided into nine strata. Within each stratum, one sample site has been selected according to the rule for a random sampling plan, but more than one could be selected (see, for example, Delmelle, 2009: pp. 188–189). **Figure 1(c)** shows one type of systematic sampling – the centric systematic sampling plan. The region has been divided into square strata and the central point in the strata selected. This method of sampling contains no randomization. However, randomization can be introduced by randomizing on the location of the first sample point (the random start method). The other $(n-1)$ sample points occupy the same relative locations in the remaining $(n-1)$ strata. There are several variants of the systematic sampling scheme (Koop, 1990). Stratified random and systematic sampling both raise questions about the size and shape of the strata to use. The hexagon and the triangle are common choices. An understanding of the process generating the quantities of interest may help in deciding these parameters of the sampling plan (Cressie, 1991). For example, the size of the strata is often chosen so that the distances between sample points are large enough so that sample values are independent – in the language of geostatistics, intersample distances are equal to or greater than the range. A pilot survey may be important in helping to decide on

Figure 1 Spatial sampling. (a) Random. (b) Stratified random. (c) Centric systematic.

the size of the strata and hence what density of points is needed.

In addition to these sampling plans there are others that may be appropriate in particular circumstances, although there are sometimes problems associated with computing sampling variances and hence interpreting results. Cluster sampling involves grouping the population into clusters. These clusters are often defined so that subsets of individuals comprising the population are spatially close together within any one cluster. First the clusters are sampled and then the sample is drawn by selecting, usually at random, individuals from within the selected clusters. This sampling method is often cheaper and administratively easier to implement. Kahn and Sempos (1989) give the example of a health survey involving a large number of economically similar but geographically dispersed villages. Instead of drawing the sample of size n from all of the villages (which could involve visiting a large number, incurring considerable time and travel costs), a subsample of villages is drawn and the sample of size n is drawn from within this subset of villages.

Nested sampling may be used where variation in the quantity of interest is associated with different spatial scales – for example, different administrative tiers of a political system. Nested sampling may be employed, again to help keep down the time and cost of the sampling exercise. The area is subdivided at the first (highest) tier of the system and units are chosen at random (similar to cluster sampling). Then these selected areas are subdivided at the second tier and these in turn are sampled – and so on until the lowest tier is reached. Within the selected areas at the lowest tier, individuals are sampled (Figure 2(b)). As can be seen from Figure 2(b), this method does not control for distance between the sample points, so that if scales of variation vary continuously (rather than in terms of discrete hierarchical levels), as might be likely to arise with a surface of values, then this method of sampling may obscure the different scales of variation. Fixed-interval point sampling, as illustrated in Figure 2(a), avoids this problem. The distance between sample points is fixed at those intervals the investigator wishes to study closely (Oliver and Webster, 1986).

When sampling for the purpose of map construction, progressive spatial sampling may be useful. The sampler begins with a coarse grid of sample points across the study area, but in those subareas where spatial variation exceeds a threshold, sampling density is increased in order to better capture gradients (Figure 3). These ideas underlie adaptive spatial sampling, where the location of each new sample point depends on the findings from previously collected samples. Delmelle (2009: pp. 197–199) illustrates cluster adaptive sampling, where the aim is to delimit an area of excess risk such as contaminated land (Figure 4). After a first wave of sampling identifies locations where contamination levels exceed a specified threshold, additional samples are taken around these locations, with further samples beyond these until the level falls below the threshold (Cox, 1999). Haining (2003: pp. 109–111) reviews a Bayesian methodology suggested by Switzer to focus sampling in the search for rare archaeological artifacts.

Spatial Variation and Sampling Plans

Two characteristics of spatial variation have a particular impact on the choice of sampling plan: spatial heterogeneity and spatial autocorrelation. The spatial distribution of an attribute is said to be heterogenous if its properties (e.g., its mean or variance) vary across the study area. The presence of spatial heterogeneity often necessitates the partition of the study area into homogenous or quasihomogenous subareas (Wang et al., 2010). Spatial autocorrelation, on the other hand, and positive spatial autocorrelation in particular, which is the form most often encountered in practical situations, is the tendency for areas or sites that are geographically close together to have similar values. The presence of spatial autocorrelation in a population to be sampled has important implications for

Figure 2 Spatial sampling. (a) Fixed interval. (b) Nested hierarchical.

the sampling variance of the estimator. Before discussing this it is necessary to distinguish between estimating surface properties in the case of the design-based approach (for example, estimating $m(R)$) and estimating underlying parameters in the case of the model-based approach (for example, estimating μ). We consider the design-based approach first.

If the purpose is to estimate $m(R)$, then the presence of positive spatial autocorrelation implies that each sample point carries information not only about its own site but also some information about neighboring site values. Consider the three sampling plans described in Figure 1. If values are positively spatially autocorrelated, one of the problems with random sampling is that because adjacent values will be similar there will be information redundancy in the case of those sample points that happen to be close together. It is also evident from Figure 1(a) that the random sampling plan leaves areas unsampled. Both of these problems with the random sampling plan are reduced to some extent by the introduction of strata, but as is clear in Figure 1(b) there are still some sample points that are close together, resulting in some information redundancy, and there are still some areas of the map not sampled – albeit smaller in extent. Systematic sampling, especially using the centric or the random start methods, reduces both effects. Intuitively we therefore expect that for a given sample size n, systematic sampling ought to produce estimates with lower sampling variances of a quantity such as $m(R)$. This, by and large, proves to be the case, because separating the sample sites in this way reduces possible redundancy in the information content of the sample (which occurs when sample observations are spatially autocorrelated). However, while the gains of moving from random to either stratified random or systematic sampling are considerable, the gains of systematic sampling over stratified random sampling are generally much smaller and seem to depend quite critically on the specific form of the underlying spatial autocorrelation (Ripley, 1981; Matern, 1986; Dunn and Harrison, 1993).

Figure 3 Progressive sampling. Systematic sampling initially with increased sampling density where stronger spatial variation is encountered. Reproduced with permission from Delmelle, E., 2009. Spatial sampling. In: Fotheringham, A., Rogerson, P. (Eds.), The SAGE Handbook of Spatial Analysis. SAGE, Los Angeles, pp. 183–206. (Figure 10.5.)

The sampling variance is estimated in the case of random sampling using:

$$\sum_{i=1}^{n}\left[z(s_i)-\overline{Z}\right]^2/(n-1) \qquad [2]$$

where

$$\overline{Z}=\frac{1}{n}\sum_{i=1}^{n}z(s_i)$$

Equation [2] provides an unbiased estimator in this case, and Ripley (1981) discusses related methods for estimating the sampling variance under stratified random and systematic sampling.

The presence of spatial autocorrelation has implications for other sampling plans. In the case of cluster sampling, a critical factor is between-cluster and within-cluster variation. If the clusters are just random assemblages of individuals in the population, then cluster sampling (with random selection of individuals from within each selected cluster) ought not to produce sampling variances any greater than, say, random sampling. If all the clusters differ greatly, then selecting a sample of them will not lead to good population estimates. If clusters have internal positive spatial autocorrelation (so that they are more homogeneous than the population as a whole), then cluster-sampling variance is likely to be bigger than random sampling. In the case of (hierarchical) nested sampling, if the population shows spatial autocorrelation, then again there will be information redundancy because some sample sites are close together. This effect may be somewhat less of a problem in the case of fixed-interval point sampling as a result of keeping sample sites apart.

In the model-based approach, if the purpose is to estimate the mean, μ, of a spatially autocorrelated model using the sample mean, then this estimator's sampling variance is inflated relative to its sampling variance under the assumption of a population that is independent. If eqn [2] is used as the estimator of the sampling variance, it can severely underestimate the true sampling variance of the sample mean. Although the sample mean is an unbiased estimator of μ, the best linear unbiased estimator (BLUE) is usually preferred, although it requires the correct specification of the underlying spatial model (see eqn [1]). As noted, the choice of sampling plan tends to be of secondary interest, but careful specification of the required sample size is needed if parameters are to be estimated to the desired level of precision (Haining, 1988).

Figure 4 Cluster adaptive sampling. A site is fathomed (+) when its toxicity rate does not exceed the contamination value. Reproduced with permission from Delmelle, E., 2009. Spatial sampling. In: Fotheringham, A., Rogerson, P. (Eds.), The SAGE Handbook of Spatial Analysis. SAGE, Los Angeles, pp. 183–206. (Figure 10.6.)

In addition to undertaking sampling to estimate nonspatial properties of an attribute, sampling may be needed in order to estimate spatial properties (the correlogram or semi-variogram) or to construct maps based on optimal interpolation. Evidence suggests that particularly for optimal interpolation and for constructing contour maps for a variable, centric systematic sampling grids are best with a density chosen to achieve required levels of precision across the map and with a rectangular grid selected for practical reasons (Webster and Burgess, 1981). Interpolation error will vary across the map as a function of the density of sample points and the effect of the survey boundary. If anisotropy is present (directional differences in the autocorrelation structure) and/or heterogeneity, then both alignment and grid specification for the systematic sample will need to reflect these characteristics (McBratney et al., 1981).

Abstract

While adjustment for spatial dependence has long been mandated in different fields, spatial statistical models refer to modeling and data analysis of processes displaying spatial dependence. This article reviews the basics of spatial random processes, compares different aspects of spatial statistical models, and investigates several topics of spatial prediction (kriging, trend models, and multivariate methods). Bayesian spatial statistics and spatial point processes are also discussed. This article concludes with recent advances in spatial statistics, including spatial–temporal statistics, dimension reduction, and nonparametric methods.

Spatial statistics is characterized by modeling and data analysis for processes displaying spatially indexed dependence structures. Adjustment for spatial dependence has long been mandated in many disciplines. The very nature of *geography* is spatial. F. Stephen (1934) noted "… Data of geographic units are tied together… in dealing with social data, we know that by virtue of their very *social* character, persons, groups, and their characteristics are interrelated and not independent." In the context of agricultural field experiments, R.A. Fisher (1935) described the basic intuition underlying much of spatial statistics: "After choosing the area we usually have no guidance beyond the widely verifiable fact that patches in close proximity are commonly more alike, as judged by the yield of crops, than those which are far apart." Though Fisher developed randomized experimental designs to avoid explicitly modeling spatial dependence, agricultural applications are an important motivation for spatial statistics (Besag, 1991).

In the early 1950s the South African mining engineer D.G. Krige pursued methods for the spatial interpolation of data with the intent of predicting the distribution of ore (e.g., gold) in space. G. Matheron (France) extended that work, formalizing mining *geostatistics*, and coined the term 'kriging' to refer to a class of spatial prediction methods. In parallel, L.S. Gandin (Soviet Union) developed essentially the same procedures for applications in meteorology where they are known as *optimal interpolation* and *objective analysis*.

While basic geostatistical methods remain very useful, the methodology was limited in terms of (1) applicability, since the analyses were historically confined to *linear models* and (2) volume of data analyzed. Technological advances regarding both data collection methods and computation have led to expansion of applications and methods of spatial statistics. For example, *image analysis* is and will continue to be a critical research area. Problems include satellite *remote sensing* of the Earth's environment and ecology, including humans and their behavior and impacts; analysis of astronomical images from optical, radio wave, infrared, and related instruments; magnetic resonance imagery; and computer vision. Methods for *image restoration* (filtering out noise), *classification*, and *object identification* are sought. Similarly, the development of *geographic information systems* is a watershed of geographically referenced data, though the efficient extraction of information from such massive datasets offers new statistical challenges.

Spatial statistics also includes modeling and analysis of mapped *point processes*, in which the locations of observations are themselves random. For example, observations may include the locations and characteristics of trees in a forest (Stoyan and Penttinen, 2000) or positions and types of galaxies in space (Feigelson and Babu, 1992). For applications in archaeology, see Hodder and Orton (1976). Searching for patterns and *clusters* of data are key challenges. An introduction to spatial modeling of *random objects* can be found in Cressie (1993).

Perspectives and Comparisons

Let D denote a collection of *sites* or *locations*, denoted by s, distributed in space. (Formally, D is taken to be a subset of d-dimensional Euclidean space. This permits mathematical consideration of the differences and distances between sites.) In geostatistics, D is often a collection of sites on the surface of the Earth, indexed in two dimensions either by s = (latitude, longitude) or by Cartesian coordinates $s = (x, y)$, or in three dimensions with the addition of altitude or depth. In image analysis, s typically represents a *pixel* located on a discrete *lattice*. For each s in D, there exists some random quantity, $Z(s)$, of interest. The stochastic process $\{Z(s) : s \in D\}$ is a *random field* or spatial random process. Z could be a continuous variable (e.g., temperature); a discrete variable (e.g., a binary variate indicating the presence or absence of some characteristic, or a multivalued discrete variable of *gray levels*, especially in image analysis); a mixed variable (e.g., rainfall may be zero with positive probability at a location, yet continuous, if some rain occurs). Z may also be a multivariate variable.

Goals in spatial statistical analyses include distributional modeling of spatial random processes; estimation and inference for aspects of the spatial model based on observational data; prediction at sites where observations are not available; and filtering or noise reduction. Two approaches to spatial process modeling dominate practice. In the first, *jointly* or *simultaneously* specified models for the process $\{Z(s) : s \in D\}$ are developed. For example, in much of geostatistics, the variable $Z(s)$ is decomposed into 'mean' plus 'error' components. The

modeling challenge is the development of joint distributional information for the errors across space. A second strategy is to build *conditionally* specified models by modeling *local* dependence structures. This track directly builds on the intuition that variables in close spatial proximity tend to be related. This is quantified by formulating distributional features of $Z(\mathrm{s})$, *conditional* on the rest of the Z process but actually depending only on the values of Z at locations in a *neighborhood* of s. Practical modeling often focuses on specification of conditional means and variances. At least two important issues arise. First, to enable spatial prediction accompanied by meaningful measures of uncertainty, a conditionally specified model should correspond to a proper joint distribution. To that end conditionally specified *Markov random fields* are often used since there is a well-developed theory regarding the existence of implied joint models (e.g., Cressie, 1993: Chapter 6). Such models are readily analyzed by Markov chain Monte Carlo methods. The second issue involves dealing with variables located near the *boundary* of D, since this region typically dictates local dependence structures that are by nature different from those in the interior of D.

The primary goal in typical problems (e.g., geostatistics) is spatial prediction. Based on a vector of n observations, $\mathcal{Z} \equiv (Z(\mathrm{s}_1), \ldots, Z(\mathrm{s}_n))'$, we seek predictions of $Z(\mathrm{s}_0)$ where s_0 is an arbitrary site in D. Depending upon the level of assumptions made, two essential principles guide the predictive analysis. First, in analyses based on assumptions asserting only the trend and covariance structures, most predictions are derived as *best linear unbiased predictions* (BLUP). 'Best' refers to the property of having smallest prediction variance among all linear, unbiased predictors. In analyses which also include distributional assumptions, predictive analyses are based on the implied conditional distribution of $Z(\mathrm{s}_0)$ given the observed data $\mathcal{Z}$. For example, assuming mean squared prediction error as the criterion for assessing the quality of prediction, the optimal predictor is $\widehat{Z}(\mathrm{s}_0) = E(Z(\mathrm{s}_0)|\mathcal{Z})$; that is, the conditional mean of $Z(\mathrm{s}_0)$ given the data.

Both Bayesian and non-Bayesian viewpoints are applied in spatial statistics. Since most strategies view the primary variable of interest Z as *random*, the principle that spatial prediction is based on the conditional distribution, or at least its moments, of the unobserved variables given the data is clearly tied to the Bayesian view in both interpretation and computational techniques. This is particularly evident in image analysis, where a potentially nonrandom, 'true image' is modeled as a realization of a stochastic spatial process (e.g., Geman and Geman, 1984; Besag, 1989). On the other hand, despite similar stochastic modeling of the primary variables of interest, the origins of geostatistics and spatial point process analysis appear to be primarily non-Bayesian in language and spirit. In particular, early approaches to model fitting and parameter estimation were primarily non-Bayesian, though their interpretation as *empirical Bayesian* is quite natural. With the advent of powerful Bayesian computational strategies (i.e., Markov chain Monte Carlo), the Bayesian approach has emerged as a critical tool in applications of all areas of spatial statistics. It offers opportunities for effective analyses in complex spatial problems, including multivariate and inhomogeneous datasets and data types, as well as nonlinear and non-Gaussian datasets.

Spatial Random Fields

Assuming all quantities exist, let $\mu(\mathrm{s})$, $\mathrm{s} \in D$ be the mean (expected value) $\mu(\mathrm{s}) = E(Z(\mathrm{s}))$, and let $\mathrm{cov}(Z(\mathrm{s}), Z(\mathrm{s}'))$, defined for all pairs of sites s and s′ in D, be the covariance function of the process.

The process is (second-order or weakly) *stationary* if it has constant mean $\mu(\mathrm{s}) \equiv \mu$ and

$$\mathrm{cov}(Z(\mathrm{s}), Z(\mathrm{s}')) = C(\mathbf{h}), \quad \text{for all} \quad \mathrm{s} \in D, \mathrm{s}' \in D \qquad [1]$$

where $\mathbf{h} = \mathrm{s} - \mathrm{s}'$. That is, the covariance between $Z(\mathrm{s})$ and $Z(\mathrm{s}')$ depends on the locations only through their difference. Note that this implies that the variance of $Z(\mathrm{s})$, $\sigma^2(\mathrm{s}) \equiv \sigma^2$, is constant. The function $C(\mathbf{h})$ is known as the *covariogram*. *Strict* or *strong stationarity* involves similar requirements applied to the joint distributions of $\{Z(\mathrm{s}) : \mathrm{s} \in \mathcal{D}\}$ as opposed merely to first and second moments (Cressie, 1993: Section 2.3).

Alternatively, again assuming that $\mu(\mathrm{s}) \equiv \mu$, the process is *intrinsically stationary* if

$$\mathrm{var}(Z(\mathrm{s}) - Z(\mathrm{s}')) = 2\gamma(\mathbf{h}), \quad \text{for all} \quad \mathrm{s} \in D, \mathrm{s}' \in D \qquad [2]$$

The function $2\gamma(\mathbf{h})$ is known as the *variogram*; $\gamma(\mathbf{h})$ is the *semivariogram*.

If the process is stationary, then calculation implies

$$.5\ \mathrm{var}(Z(\mathrm{s}) - Z(\mathrm{s}')) = C(0) - C(\mathbf{h}) = \gamma(\mathbf{h}) \qquad [3]$$

Hence, stationarity implies intrinsic stationarity. However, variograms satisfying [2] may exist in some cases for which covariograms do not exist. For stationary processes, [3] allows one to view modeling covariograms and variograms as being equivalent, though some have argued that estimation based on data is enhanced for the variogram.

An intrinsically stationary process is *isotropic* if $\gamma(\mathrm{s} - \mathrm{s}') = \gamma(h)$ for all pairs of sites, where h is the *distance* between them. That is, the variogram depends only on the distance between sites (i.e., the length of the vector $\mathbf{h} = \mathrm{s} - \mathrm{s}'$), but not their relative directions. *Anisotropy* (the violation of isotropy) arises for processes that develop differentially in different directions of space (Cressie, 1993: Section 2.3). For example, temperature values, or variables depending upon temperature (e.g., type of agriculture, ecology, etc.), are roughly moderated by latitude. Hence, north–south covariance structures might well be different from their east–west counterparts. An example of an isotropic semivariogram is the *exponential model*:

$$\gamma(h) = \begin{cases} 0 & \text{if } h = 0 \\ \gamma_0 + \gamma_1\left(1 - \mathrm{e}^{-h/a}\right) & \text{if } h > 0 \end{cases} \qquad [4]$$

where $a > 0$. Note that as $h \to 0$, $\gamma(h) \to \gamma_0$, rather than 0. This discontinuous behavior, known as the *nugget effect*, occurs in a variety of commonly used semivariograms. Physically, γ_0 has been interpreted as arising from (1) very small-scale fluctuations in the Z process and/or (2) measurement error. However, if the process modeled is a sufficiently smooth function of space, the only mathematically valid explanation for the nugget effect is measurement error.

The exponential covariogram corresponding to [4] is

$$C(h) = \begin{cases} \gamma_0 + \gamma_1 & \text{if } h = 0 \\ \gamma_1 \mathrm{e}^{-h/a} & \text{if } h > 0 \end{cases} \qquad [5]$$

Another covariogram sometimes used is the *Gaussian model*:

$$C(h) = \begin{cases} \gamma_0 + \gamma_1 & \text{if } h = 0 \\ \gamma_1 e^{-h^2/b} & \text{if } h > 0 \end{cases} \quad [6]$$

where $b > 0$. (Use of the modifiers 'exponential' and 'Gaussian' accrues from similarities to the exponential and Gaussian probability density functions, rather than distributional assumptions for Z.) A very rich class of isotropic covariograms is the *Matérn class*, written here without a nugget for comparison:

$$C(h) = \frac{2\sigma^2}{\Gamma(\nu)}\left(h\sqrt{\nu}/a\right)^{\nu} K_{\nu}\left(2h\sqrt{\nu}/a\right) \quad [7]$$

where $\nu > 0$, σ^2 is the variance of $Z(\mathrm{s})$, $\Gamma(\cdot)$ is the usual gamma function, and $K_{\nu}(\cdot)$ is the modified Bessel function of the second kind.

Spatial Prediction

A standard spatial model takes the form

$$Z(\mathrm{s}) = \mu(\mathrm{s}) + \varepsilon(\mathrm{s}) \quad [8]$$

where $\mu(\mathrm{s})$ is a spatial mean model and $\varepsilon(\mathrm{s})$ is a zero-mean spatial error process. Critical issues involve the choices of models regarding both the mean or *trend* (also known as *drift*) $\mu(\mathrm{s})$ and the error process $\{\varepsilon(\mathrm{s}) : \mathrm{s} \in \mathcal{D}\}$. Such modeling is challenging in that both components explain aspects of the spatial structure present in Z. The conventional guideline is that the trend reflects large-scale spatial variation while the error process explains residual small-scale spatial dependence. Implementation of this guideline and interpretation of results vary with the context as well as the goals and knowledge of the analyst. As noted by Cressie (1993, p. 25), "What is one person's (spatial) covariance structure may be another person's mean structure." Also, note that in modern statistical approaches, trend models based on both spatial location and covariates are recommended. Trend models can also be incorporated in conditionally specified models, either via conditionally specified mean models, or with globally specified mean models and conditionally specified error models.

The Basics of Kriging

Ordinary kriging asserts a constant trend model. Linear predictors take the form

$$\widehat{Z}(\mathrm{s}_0) = \sum_{i=1}^{n} \lambda_i Z(\mathrm{s}_i) \quad [9]$$

The unbiasedness condition, $E(\widehat{Z}(\mathrm{s}_0)) = \mu$, adds the side condition that $\sum_{i=1}^{n} \lambda_i = 1$. Minimization of the predictive variance (or mean squared prediction error)

$$E\left(Z(\mathrm{s}_0) - \widehat{Z}(\mathrm{s}_0)\right)^2$$

subject to the side condition yields simple formulas for the optimal values of the λ_i as appropriate functions of the covariance function. Alternatively, the formula can be written in terms of the variogram, enabling spatial prediction for processes that are intrinsically stationary (Cressie, 1993, p. 121–123). The achieved optimal value of the predictive variance is then used to measure the precision of the prediction.

The kriging formulas are derived under the assumption that the variogram or covariance function is known. Typically, data-based estimates of these functions are simply plugged into the kriging formulas. A variety of methods for estimation of the variogram (or covariogram) have been suggested. A simple procedure is to apply a method-of-moments notion: an empirical version of the semivariogram is

$$\widehat{\gamma}(\mathbf{h}) = \frac{\sum_{n(\mathbf{h})}\left(Z(\mathrm{s}_i) - Z(\mathrm{s}_{i'})\right)^2}{\#n(\mathbf{h})} \quad [10]$$

where the sum is taken over those data points satisfying $\mathrm{s}_i - \mathrm{s}_{i'} = \mathbf{h}$ and $\#n(\mathbf{h})$ is the number of such pairs of data points. A simple estimate of the covariogram is

$$\widehat{C}(\mathbf{h}) = \frac{\sum_{n(\mathbf{h})}\left(Z(\mathrm{s}_i) - \overline{Z}\right)\left(Z(\mathrm{s}_{i'}) - \overline{Z}\right)}{\#n(\mathbf{h})} \quad [11]$$

where $\overline{Z}$ is the simple mean of the observed values. However, since there are only n observations, these estimates cannot provide estimates for all $\mathbf{h}$. Practical estimates are typically constructed based on *binning* procedures. For example, under the additional assumption of isotropy, consider a collection of M nonoverlapping intervals

$$I_m = [h_m - \delta_m, h_m + \delta_m]; m = 1, \ldots, M$$

For each interval the above empirical sums and counts of pairs are taken over all pairs separated by distances in I_m. The resulting M values can then be smoothed to produce a function estimate.

The above estimates suffer from a variety of deficiencies, especially if the sample size n is small. A variety of alternatives have been suggested. One general approach is to *parameterize* the covariogram (or variogram), specifying it to be a member of some class (the Matérn class [7] is a popular choice). Methods for parameter estimation include least squares, weighted least squares, and maximum likelihood. A second avenue for estimation involves the use of nonparametric function estimation, especially in the context of estimating the spectral representation of the covariogram. Also, robust estimates with respect to outlying observations have been developed. See Cressie (1993) and Stein (1999) for further discussion of classes of variograms and estimation procedures. Sampson and Guttorp (1992) consider estimation in the nonstationary case.

Trend Models and Their Estimation

Universal kriging refers to spatial prediction based on trend models of the form

$$\mu(\mathrm{s}) = \sum_{j=0}^{p} f_j(\mathrm{s})\beta_j \quad [12]$$

where the $f_j(\cdot)$ are $p+1$ specified functions of space and $\boldsymbol{\beta} = (\beta_0, \ldots, \beta_p)'$ is a vector of $p+1$ unknown parameters. In vector notation, let $\mathbf{f}(\mathrm{s}) = (f_0(\mathrm{s}), \ldots, f_p(\mathrm{s}))'$, so the model is written compactly as

$$\mu(\mathrm{s}) = \mathbf{f}'(\mathrm{s})\boldsymbol{\beta}$$

Ordinary kriging is included by assuming $f_0(\mathrm{s}) = 1$ and $p = 0$.

A common example is a quadratic trend surface model: writing locations in Cartesian coordinates $\mathrm{s} = (x, y)$, assume that

$$\mu(\mathrm{s}) = \beta_0 + \beta_1 x + \beta_2 y + \beta_3 x^2 + \beta_4 xy + \beta_5 y^2$$

In addition to higher order polynomial trends, nonpolynomial models, such as *local polynomials* have been considered. The use of *splines* is highly related; see Wahba (1990) and Cressie (1993, p. 180–183).

Representation of the kriging model in matrix form provides a better understanding and enables parallels to familiar statistical linear regression modeling. The notation $\mathbf{X} \sim (\mathbf{m}, \mathbf{C})$ is read 'the random vector $\mathbf{X}$ has a multivariate distribution with mean $\mathbf{m}$ and covariance matrix $\mathbf{C}$.' The notation $\mathbf{X} \sim N(\mathbf{m}, \mathbf{C})$ adds the assumption that the distribution is multivariate normal. The standard universal kriging model is then

$$\begin{pmatrix} Z(\mathrm{s}_0) \\ \mathcal{Z} \end{pmatrix} = \begin{pmatrix} \mathbf{f}_0'\boldsymbol{\beta} \\ \mathbf{F}\boldsymbol{\beta} \end{pmatrix} + \begin{pmatrix} \varepsilon(\mathrm{s}_0) \\ \boldsymbol{\varepsilon} \end{pmatrix} \qquad [13]$$

where

$$\begin{pmatrix} \varepsilon(\mathrm{s}_0) \\ \boldsymbol{\varepsilon} \end{pmatrix} \sim \left(\begin{pmatrix} 0 \\ 0 \end{pmatrix}, \begin{pmatrix} \sigma^2(\mathrm{s}_0) & \boldsymbol{\sigma}' \\ \boldsymbol{\sigma} & \boldsymbol{\Sigma} \end{pmatrix} \right) \qquad [14]$$

where $\boldsymbol{\sigma}$ is the $n \times 1$ vector of covariances between errors at site s_0 and the observation sites; $\mathbf{F}$ is the $n \times (p+1)$ matrix dictated by the functions $f_j(\cdot)$ evaluated at the observation locations; and $\boldsymbol{\varepsilon}$ is the vector of errors at observation sites. These errors are assumed to have zero means and covariance matrix $\boldsymbol{\Sigma}$ whose entries are the covariances $\mathrm{cov}(\varepsilon(\mathrm{s}_i), \varepsilon(\mathrm{s}_{i'}))$ for pairs of data points.

Formulas for the optimal linear predictor or BLUP are readily derived (Cressie, 1993, p. 172–180):

$$\widehat{Z}(\mathrm{s}_0) = \mathbf{f}'(\mathrm{s}_0)\boldsymbol{\beta} + \boldsymbol{\sigma}'\boldsymbol{\Sigma}^{-1}(\mathcal{Z} - \mathbf{F}\boldsymbol{\beta}) \qquad [15]$$

These formulas depend on appropriate values of the covariance function and $\boldsymbol{\beta}$, requiring estimation of both quantities. Note that use of [15] does not require spatial stationarity of the error process, though it is often assumed in estimation.

Estimation of $\boldsymbol{\beta}$ is typically accomplished via *generalized least squares*. Since the observations follow the model

$$\mathcal{Z} = \mathbf{F}\boldsymbol{\beta} + \boldsymbol{\varepsilon} \qquad [16]$$

the generalized least squares estimate of $\boldsymbol{\beta}$ is

$$\widehat{\beta} = \left(\mathbf{F}'\boldsymbol{\Sigma}^{-1}\mathbf{F}\right)^{-1}\mathbf{F}\boldsymbol{\Sigma}^{-1}\mathcal{Z} \qquad [17]$$

Estimation of the covariogram of the $\boldsymbol{\varepsilon}$ process proceeds as discussed earlier, though now the data used are the residuals from the fitted trend model: $\mathcal{Z} - \mathbf{F}\widehat{\beta}$. However, there is a clear difficulty. The very residuals needed to estimate the covariogram depend on the covariogram since $\widehat{\beta}$ is a function of $\boldsymbol{\Sigma}$. A variety of approaches to this problem have been suggested. One is to use some preliminary guess at $\boldsymbol{\Sigma}$ in [17], but base prediction formulas on the estimated covariogram of the resulting residuals. With the increase of readily available computation, the more modern approach *iterates* between generalized least squares estimation of β and covariogram estimation until some stability is achieved. Note that the extra uncertainty accruing from the use of data-based estimates of β and the covariance function is seldom accounted for in classical kriging.

Treatment of measurement error can be included in the modeling. Rather than observing $\mathcal{Z}$ directly, the observed data values, denoted by Y, may be modeled as $Y(\mathrm{s}_i) = Z(\mathrm{s}_i) + e(\mathrm{s}_i)$; $i = 1, \ldots, n$. Let $\mathcal{Y}$ denote the $n \times 1$ vector of observations. In matrix form we write

$$\mathcal{Y} \sim (\mathcal{Z}, \mathbf{D}_\gamma) \qquad [18]$$

where $\mathbf{D}_\gamma$ is the covariance matrix of the measurement errors $\mathbf{e} = (e(\mathrm{s}_1), \ldots, e(\mathrm{s}_n))'$. A common, but not unequivocal, assumption is that $\mathbf{D}_\gamma = \sigma_\gamma^2\mathbf{I}$ (i.e., the measurement errors are mutually uncorrelated). Also, assume $\mathbf{e}$ is uncorrelated with $\mathcal{Z}$. If Z is a smooth function of space, σ_γ^2 is a quantification of the nugget effect. To complete the formalization, interpret [18] as a specification *conditional* on $\mathcal{Z}$. The model [16] for $\mathcal{Z}$ implies that the *unconditional* model for $\mathcal{Y}$ is

$$\mathcal{Y} \sim \left(\mathbf{F}\boldsymbol{\beta}, \boldsymbol{\Sigma} + \sigma_\gamma^2\mathbf{I}\right) \qquad [19]$$

(Compare this covariance matrix to the piecewise definitions of variograms in [5] and [6].) Without replicate observations at some of the observation locations, σ_γ^2 is not directly estimable in classical kriging. Typically, estimates are obtained by extrapolation of covariogram estimates for small distances.

Note that the goals of the analysis now include not only prediction of $Z(\mathrm{s}_0)$, but also prediction of $\mathcal{Z}$. Predicting $\mathcal{Z}$ based on $\mathcal{Y}$ provides *spatial smoothing*, as opposed to *spatial interpolation* when σ_γ^2 is assumed to be zero.

Multivariate Methods

In many applications, several variables may be of interest, suggesting the consideration of a random vector, $\mathbf{Z}(\mathrm{s}) = (Z_1(\mathrm{s}), \ldots, Z_K(\mathrm{s}))'$. In mining, the data might consist of measurements of amounts of K minerals at each observed site. In meteorology, data on temperature, pressure, and precipitation are often collected. In satellite imaging, multichannel sensors collect intensities in various bandwidths.

The classical geostatistical treatment of multivariate spatial data is known as *cokriging*. The modeling strategy is a direct generalization of the univariate case. For each coordinate $Z_k(\mathrm{s})$ of $\mathbf{Z}(\mathrm{s})$, consider a mean or trend model (see [12]),

$$\mu_k(\mathrm{s}) = \mathbf{f}_k'(\mathrm{s})\boldsymbol{\beta}_k, k = 1, \ldots, K \qquad [20]$$

Note that the spatial regression functions comprising the various f_k need not be the same for all k; indeed, the dimensions of the β_k may vary with k. The key second-order parameters are the covariance matrices,

$$\mathrm{cov}(\mathbf{Z}(\mathrm{s}), \mathbf{Z}(\mathrm{s}')) = \mathbf{C}(\mathrm{s}, \mathrm{s}'), \mathrm{s} \in D, \mathrm{s}' \in D \qquad [21]$$

The principles and basic formulas for best linear unbiased prediction remain essentially the same as for the univariate case. Since the notation is cumbersome, the reader is referred to Wackernagel (1995) for details.

Practical implementation of cokriging can be difficult. First, specification and subsequent estimation of $\mathbf{C}(\mathrm{s}, \mathrm{s}')$ is problematic, in that it involves specification not merely of K spatial

covariance functions (one for each variable) but also, $.5K(K-1)$ *cross-covariance functions*, one for each pair Z_k, $Z_{k'}$, $k \neq k'$. The number of observations critically limits the ability to estimate the required covariance functions. Indeed, sample size typically mandates the need for extremely simple, often implausible, covariance models and/or a reduction in K. Further, the sampling pattern (e.g., observations of only some coordinates of $\mathbf{Z}$ at some sites) can moderate the ability to estimate parameters and predict.

An alternative modeling strategy is to build multivariate models *hierarchically*; namely as a sequence of conditional models. A precursor to this view from the geostatistics literature is *kriging with external drift*. For example, suppose that spatial prediction of near-surface ozone is of interest. It is well accepted that temperature is predictive for ozone. Hence, spatial prediction of ozone could be enhanced if appropriate temperature data were available and included in the model. An elementary approach is to view temperature as a (fixed) covariate and to include it in the formulation of a universal kriging model for ozone. Next, suppose temperature observations are unavailable at sites at which ozone predictions are sought. One could essentially form a kriging model for temperature, and rely on temperature predictions to produce ozone predictions. These notions can be made rigorous statistically. Specification of a complete spatial model for ozone conditional on temperature combined with a marginal spatial model for temperature does imply a joint model for both, as might be formed in a cokriging approach. However, the parameterizations of the models can be different. In particular, rather than direct specification and estimation of the cross-covariance function for ozone and temperature, one specifies a conditional mean relationship between the two. For further discussion and examples see Royle and Berliner (1999).

Bayesian Spatial Statistics

Bayesian Geostatistics

Models for the Z process, such as the basic model [13] along with a measurement error stage as in [18] can readily be posed in the Bayesian framework. Process models for Z are viewed as *priors*; these priors may be simultaneously or conditionally specified. Specification of prior distributions on model parameters, such as the trend model coefficients $\boldsymbol{\beta}$, measurement error variance, and parameters of the modeled covariance function are also formulated. Predictive inference is then based on the posterior distribution of unknown quantities given the data. (A general review of Bayesian analysis is given in Bernardo and Smith, 1994.)

Direct analogs to conventional kriging often rely on multivariate normal distributions in both [13] and [18]. This imposition of distributional assumptions has been criticized. However, neither standard kriging nor Bayesian analyses based on normal distribution assumptions are recommended for highly non-normal data and processes. The Bayesian approach readily offers valid measures of uncertainty (e.g., Le and Zidek, 1992; Handcock and Stein, 1993) unlike those arising from the 'plug-in' of estimates procedures dominating non-Bayesian kriging.

With the advent of Bayesian computing advances, non-normal models can be analyzed. For example, settings in which the Z variable is discrete, such as in some imaging problems (Geman and Geman, 1984) or is count data modeled as via Poisson or related distributions (Kaiser and Cressie, 1997; Wolpert and Ickstadt, 1998), have been considered. Also, see Diggle et al. (1998).

Hierarchical Models

Bayesian hierarchical models for collections of variables are combinations of component models or *stages*. Specifically, a joint distribution for all uncertainty quantities is constructed as a product of conditional distributions. Motivations for hierarchical modeling include:

- individual stages often are formulated more easily than is the full joint model directly;
- scientific understanding of the relationships among variables is often readily available for components of the model;
- combining datasets consisting of very different types of data is often enhanced.

The first stage of a Bayesian hierarchical model is usually a *data model*; i.e., a measurement error model for the observations conditional on processes and parameters of interest (see [18]). In higher level stages, *process model priors* are formed to model and interrelate spatial processes, including latent processes and spatial random effects. By separating models of the data and the processes of interest, we often can incorporate science ranging from qualitative understanding to the use of underlying differential equations in modeling those processes; for examples of each notion see Royle and Berliner (2005) and Wikle and Berliner (2005), respectively. Finally, a *parameter model* specifies a prior probability distribution for all model parameters. See Banerjee et al. (2014) and Berliner (2000) for review and references.

The simultaneous developments of Bayesian hierarchical models and computational strategies to implement them have revolutionized the quality and range of problems we address in spatial and spatial–temporal statistics.

Spatial Point Processes

A spatial point process arises when the locations of events occur randomly in D. Basic data take the form $(s_1, \ldots, s_N)'$, where the number of locations, N, is a random variable.

The probability theory for point processes typically formulates a model for random points in $\mathcal{R}^2$. The model then implies a distribution for N, the number of events in the study region D, a bounded subset of $\mathcal{R}^2$, as well as the joint distribution of their locations. Generally, the treatment of edge effects then becomes a challenge (Ripley, 1988: Chapter 2).

A standard point process model is the homogeneous Poisson spatial process with intensity λ: for any k and any selection of disjoint subsets $A_1, \ldots, A_k$ of $\mathcal{R}^2$, assume that the numbers of events, $N(A_i)$, $i = 1, \ldots, k$, are independent random variables, each with probability

$$P(N(A_i) = n) = \frac{(\lambda|A_i|)^n}{n!}\exp(-\lambda|A_i|), n = 0, 1, \ldots, \quad [22]$$

where $|A_i|$ is the area of A_i, $\int_{A_i} \mathrm{ds}$. Note that for any set A, the mean $E(N(A)) = \lambda|A|$. The Poisson process is viewed as *completely spatially random*, since counts in disjoint intervals are independent and the probabilities in [22] depend only on A_i through its area and not its shape or position. This model is often used as a *null hypothesis*. Rejection of the Poisson model suggests that the process has some spatially dependent structure, or dependence among separated regions. Numerous generalizations have been considered. The Poisson *cluster process* allows cluster locations to be distributed according to one Poisson spatial process while events in clusters are distributed according to another Poisson model. Extensions to alternative measures on sets beyond simple area, including measures which vary in space leading to *inhomogeneous processes* have been considered. A *Cox process* is generated as a Poisson process, but the measures associated with sets are themselves random.

As in geostatistics and related areas, selected moments of a spatial process play roles in both theory and data analysis. Define the *intensity function* of a point process as

$$\lambda(\mathrm{s}) = \lim_{|\mathrm{ds}|\to 0} \frac{P(N(\mathrm{ds}) > 0)}{|\mathrm{ds}|} \quad [23]$$

where ds is a small square centered at s. If only one event may occur at a location, note that

$$\lambda(\mathrm{s}) = \lim_{|\mathrm{ds}|\to 0} \frac{E(N(\mathrm{ds}))}{|\mathrm{ds}|}$$

The second-order product density of a point process is

$$\lambda_2(\mathrm{s}, \mathrm{s}') = \lim_{|\mathrm{ds}|\to 0, |\mathrm{ds}'|\to 0} \frac{E(N(\mathrm{ds})N(\mathrm{ds}'))}{|\mathrm{ds}|\ |\mathrm{ds}|} \quad [24]$$

If $\lambda_2(\mathrm{s}, \mathrm{s}')$ depends only on $\mathbf{h} = \mathrm{s} - \mathrm{s}'$, the process is stationary; if $\lambda_2(\mathrm{s}, \mathrm{s}')$ depends only on the distance h between the points, it is isotropic. In the isotropic case Ripley (1977) developed a theory for the *K function*,

$$K(h) = \frac{E(\text{number of other points within distance } h \text{ of an event})}{\lambda} \quad [25]$$

and its relationship to $\lambda_2(h)$. A Poisson process is isotropic with $K(h) = \pi h^2$.

The K function plays a critical role in theory, because it can be readily computed for a variety of important point processes, and in practice, because it can be readily estimated from data. Simple data-based estimates take the form

$$\widehat{K}(h) = \frac{\sum_{i=1}^{N} \text{number of other points within distance } h \text{ of } \mathbf{s}_i}{\lambda N}$$

(λ is often estimated as $N/|D|$.) Note that this estimate is negatively biased since events outside the data collection domain D are not included. The intuition behind the K function relates generally to statistical *distance methods*, and specifically, to *nearest-neighbor methods*. Distance methods involve statistics which are computed from the set of all distances between events, rather than the actual locations. Substantial theory regarding the distributions of distance-based statistics is available.

Extensions of point processes include *marked point processes* for which a (possibly multivariate) variable Z is associated with each event, leading to data of the form $\mathcal{Z} \equiv (Z(\mathrm{s}_1), \ldots, Z(\mathrm{s}_N))'$. A related multivariate class of problems involves the modeling and data analysis for multiple point processes.

Recent Advances

Spatial–Temporal Statistics

Complex model structures typically arise when both spatial and temporal dependences and their interactions are present. Early attempts in this area often viewed time as if it were another spatial dimension, leading to relatively simple treatments of spatial–temporal data via spatial methods. However, the special role of time (i.e., the direction of its flow) often renders such approaches ineffective. Alternatively, the *Kalman filter* adapted to space–time problems has had wide application in the sciences. The basic method is analogous to Bayesian kriging in temporal settings. Spatial–temporal statistics is at the forefront of current statistical research. See Cressie and Wikle (2011) for a review and references. Many of advances in spatial statistics were developed in spatial–temporal settings. Such examples and references having a strong spatial component are included here.

Dimension Reduction

As the sizes of datasets grow, many traditional spatial analyses become difficult to implement. For example, as we saw in the section 'Spatial Prediction,' most traditional methods involve the modeling, estimation, and manipulation (e.g., inversion) of covariance matrices. In very large problems all three of these facets may become very difficult. Hence, development of techniques involving dimension reduction is a primary focus of current research.

Useful classes of dimension reductions involve modeling the mean and/or covariance functions as combinations of selected basis functions. For a vector of length n, consider [8] of the form

$$\mathcal{Z} = \sum_{j=1}^{p} \phi_j a_j + \varepsilon \quad [26]$$

where the ϕ_j are $p+1$ specified basis functions, the β_j are unknown parameters, and n is extremely large compared to p. For example, the ϕ_j may be the leading $p+1$ principal components (PCs) or empirical orthogonal functions, as they are known in the geosciences, of some selection of the covariance matrix of ε. When replicates of $\mathcal{Z}$ are available, their empirical covariance matrix is usually used. The singular value decomposition can be used to define the ϕ_j even if the number of replicates is less than n, though larger than $p+1$. Berliner (2000) provide an example where $n > 2000$ and replicates were defined across time. They used a small number of the leading PCs in the mean model and the next several PCs in defining the covariance matrix of ε.

Various approaches to the selection of basis vectors have been pursued. Methods such as those of the previous

paragraph fall in the general framework of Karhunen–Loeve expansions. Other examples include wavelets and neural nets. Wikle et al. (2001) use the normal modes of a governing partial differential equation as basis functions. Further, we need not require that the basis functions are orthogonal. This opens a wide range of *kernel* basis functions. The key idea is to model $Z(s)$ as the convolution of a weighting function and a stationary, typically Gaussian process. See Higdon (1998) and Wikle and Cressie (1999).

The above discussion focused on modeling the mean. Dimension reduction is also critical in managing high-dimensional covariances. One class of approaches is *sparse models*. Specifically, a large covariance matrix is modeled as the sum of an easily inverted covariance matrix (e.g., a scalar times the identity matrix) and a sparse matrix, i.e., most of its elements are equal to zero. The sparse matrix is used to capture local-in-space covariances.

Nonparametric Bayesian Methods

Nonparametric Bayesian methods involve modeling random quantities as being generated from some probability model which in turn is assumed to be generated from a probability model. Infinite random mixtures of distributions and Dirichlet processes are common models for generating a random probability distribution. In spatial statistics, such models have proven to be very useful, especially in settings in which clustering is present; see Gelfand et al. (2005).

Extensions

The techniques for modeling means and covariances associated with spatial statistics can be applied in settings. For example, building models for processes in space by some other variable, depending on the application, is the cornerstone many approached to the design and analysis of computer experiments. See Santner et al. (2003). Further, design of data collection in spatial settings is a critical and growing area in research. Finally, challenging areas are attracting numerous research efforts. For example, the study of spatially distributed networks is particularly interesting; see Barthelemy (2010).

Spatial Thinking in the Social Sciences

Paul Claval, University of Paris-Sorbonne, Paris, France

Published by Elsevier Ltd.

Abstract

The interest of social scientists changed with time. Analyzing spatial distributions was a way to discover the relativity of human realities and their social nature. In the eighteenth century, the interest shifted toward the influence of environment on human behavior. Later, it focused on the role of distance on the way societies function. Since the 1970s, a spatial turn occurred: societies are always spatial realities; they build their environments, but depend on its natural dimension, which has to be preserved.

Space played a fundamental role in the birth of the social sciences in the eighteenth and early nineteenth centuries, since it allowed for comparative studies that were conducive to a search for explanation. Later, systematic social sciences neglected spatial problems, except for some functional approaches, which explored the role of space as environment in the evolutionist perspective of human geography or as distance as a key factor in the location of economic activity. Since the 1970s, the growing awareness of the fundamental diversity of societies, economies and polities was conducive to a rediscovery of the role of environment and distance, i.e., space, in social processes. A new interest in the sense of place – space as experience – developed also.

The objects upon which social sciences work, either people or artifacts, take up some room and are located in specific places. Cognition implies the building and mobilization of spatial skills, like orientation. Social scientists are generally more interested in particular spatial categories like direction, distance, place, area, landscape, village, town, and city than in space: the distribution of things and people, the behaviors and practices of everyday life, or the plans developed for the future deal with concrete geographical realities rather than the abstract idea of space. Even geography was traditionally more oriented toward places, regions, or zones than toward space: the idea of geography as a spatial discipline did not develop before the 1950s, and was soon criticized. Among the other social sciences, economics was the only one with a specialty branch in the field: spatial economics, which began to flourish in the 1820s. Among the cognitive sciences, the psychology of orientation developed before Jean Piaget described the stages of space construction by children. As a result, spatial thinking in the social sciences often appears split into different fields, *urban* studies, *rural* studies, *landscape* studies, the significance of the *regional approach* and of *place*, the idea of *environment*, the problem of *orientation*, etc.

Spatial thinking refers to five types of intellectual operations: (1) using geographical observations as a starting point for social analysis; (2) explaining, generally within a functional perspective, the role of different aspects of space in the life of social groups; (3) understanding the way people invest symbolic meanings in their environment; (4) wondering about the significance given to space in the definition of concepts like society, economics, culture, language, polity, etc.; or (5) deciphering the ways in which the human mind deals with space and builds and uses spatial categories. The first type was present from the earliest developments of the social sciences. The second type flourished mainly in the late nineteenth and most of the twentieth centuries. The third type is more characteristic of the rise of phenomenological approaches, since the 1930s or 1940s. The fourth type is mainly linked to the development of critical perspectives on the social sciences since the 1970s. The development of an interest for space by the cognitive sciences remained until recently independent from the other approaches.

Until the 1960s or 1970s, social sciences displayed more interest in time than in space: philosophies of history were central to Western thought. With the growing criticism of Western modernity, the situation changes. A new concern with space developed from the 1980s: a 'spatial turn.'

Spatial Distributions as a Point of Departure for Social Thinking

We are living in social systems and so deeply embedded into them that generally we think they are an expression of the natural order. In order to build a science of social realities, the social scientist has to introduce a distance between him and the object he studies. Travel narratives and geographical descriptions played a central role in this operation. Montaigne started to ponder about the relativity of social institutions when reading about the American cannibals. From Jean Bodin to Montesquieu, the diversity of political and social institutions nurtured the reflection on social and political life and was interpreted through a simple model, the influence of climate.

The first steps of economics were linked with geographic evidence: the role of transport in the distribution of economic activities; the complementarities between cities and rural areas; the economic circuit served as bases for the development of a more conceptual vision, which started with the analysis of market mechanisms by Turgot and Adam Smith's reflection on the division of labor.

With the development of travels and the improvement of their accounts, geographical comparisons became more sophisticated: they allowed for the development of new disciplines, like ethnography. The change of scenery could be provided by travel through time as well as space. Immanuel Kant emphasized the similarities between history and geography: spatial and temporal distributions were the first features to confront social scientists in their study of the world. He opposed spatiotemporal descriptions to systematic analyses.

 http://dx.doi.org/10.1016/B978-0-08-097086-8.72092-7

Partly under the influence of Kant, the idea that geography was essentially a description of spatial distributions developed and remained alive well into the twentieth century.

It was during the first decades of the nineteenth century that spatial comparisons played their most important role in the development of science. It was true for the natural sciences – Charles Darwin developed his evolutionary theory when traveling on the *Beagle*. In the social sciences, Alexis de Tocqueville built his analysis of democracy by comparing the United States, where it permeated all forms of social life, with Old Europe, where aristocrats were still influential. Karl Marx explored the opposition between medieval cities and rural areas, the Asiatic social and economic organization, and the industrial revolution in Britain before building the notion of mode of production.

By the middle of the nineteenth century, the cartographic model was increasingly replaced by models each with a logic dictated by the dynamic, immediate, interactive phenomena under study: the new specialized disciplines broke their earlier links with spatial thinking.

The Functional Approach to the Relations between Space, Social Life, and Thought

When social and behavioral sciences severed their former links with distributional approaches, they generally considered space as a neutral stand and ceased to use it as a significant factor for explaining what they observed. Many scholars thought, however, that space mattered: they had the idea that social life differed according to its physical setting, the fact that people lived in empty or overpopulated areas, and were more or less distant from each other. For Emile Durkheim the foundation of sociology lay in social morphology, but he was unable to provide a clear picture of it. The only way to take it into account was to adopt a functional perspective: space could be conceived of either as a collection of environments or a set of distances.

Space as Environment

In the environmental perspective, the emphasis was given to the local connections between people, artifacts, and place. The first environmental approaches were developed by the sensualist psychology of the eighteenth century. Man was a product of whatever his senses impressed upon his mind. His aptitudes and personality reflected his environment. If it was disorderly or unsound, social life had many reasons to be stressed. By the end of the eighteenth century, social scientists were well aware of the social and political implications of such a conception. Jeremy Bentham conceived his *Panopticon* in order to provide criminals with an environment, which would teach them safer forms of behavior. More generally, the idea that 'to reform society, you had to change its material setting' was central to the nineteenth-century utopian socialism and still present in the conception of urbanism developed by the International Movement of Modern Architecture in the 1930s.

Johann Gottfried Herder was more sensitive to the harmony, which developed between peoples and the country they lived in than to the sensual influence of these surroundings on their mind and behavior. The early development of geography in Germany was linked to the combined influence of Kant (evident in Alexander von Humboldt's conception of geographical description) and Herder (who was closer to Carl Ritter). Such a conception was important for all the social sciences in Germany, since it was conducive to a keener interest in peoples than in individuals or social classes. For many German geographers, the harmony between a people and the land they lived in was expressed through its landscapes.

The Herderian environmentalism was a literary and poetic one. Natural evolutionism had a more direct impact on the social sciences, since it was a scientific theory. The early forms of evolutionism as developed in the eighteenth and early nineteenth centuries had no direct impact on the then emerging social sciences. The publication of *The Origin of Species* occurred at a time when history and the idea of progress had become popular in the public opinion, and original forms of evolutionism had developed in sociology: hence the impact of its theses in the social sciences. For sensualist psychology or Herderian philosophy, the influence of things upon the human mind was a direct one. For scientific evolutionism, the relations were mediated through biological mechanisms.

Did environments shape completely the destiny of humankind and of any of its groups? Hot discussions developed between environmentalists and the scientists who believed in human liberty. In order to depict the relations between organisms and their environment, a new discipline, ecology, appeared. Named by Haeckel in 1866, its first scientific achievements occurred at the end of the nineteenth century; it became mature in the 1930s and 1940s. Geographers did not wait for the development of ecology to propose a new conception of their discipline: *Anthropogeographie*, or human geography, was named and shaped by Friedrich Ratzel in the 1880s and 1890s. For him and for the first human geographers in France, a strict environmentalism was an unbearable position, but physical constraints did exist and shaped at least partly human behavior and history: geographers pleaded for possibilism, which gave room to physical and biological constraints, but acknowledged the role of other variables.

By 1920, it had become evident that environmentalism was not a very fruitful way of conceiving the role of space in social functioning.

Space as Distance

Economics had developed another approach to analyze the role of space in the functioning of society. In the early nineteenth century, some economists were unhappy with the elimination of space from mainstream theory. They developed spatial economics as a sideline. It was centered on two problems: the uneven distribution of natural factors and the role of distance. The name of David Ricardo is associated with the first orientation and the ensuing theory of international specialization and trade. Johann Heinrich von Thünen explained how distances to the market determined farming specialization even in a perfectly uniform setting (1826–52). The progress of spatial economics was a slow one: people had to wait until Alfred Weber for a coherent theory of industrial location (1909), and Walter Christaller and August Lösch for an understanding of the location of service activities and the nature of urban networks (early 1930s).

At the end of the nineteenth and the beginning of the twentieth centuries, some anthropologists also considered distance as a major factor of cultural differentiation. It soon appeared that diffusionism could not serve as an overall explanatory theory. Diffusion was, however, a significant cultural process.

When geographers, tired from the hopelessly descriptive character of the possibilist approach, tried in the late 1950s and 1960s to develop a more systematic view of their scientific enterprise, many of them decided that geography should become a discipline of distances: they incorporated what spatial economics and anthropology could offer and went further through the emphasis they gave to communication processes. They used what a new scientific field, the study of communication, was developing.

The functional approach to social problems through the analysis of distance was fruitful. Its role in planning theory and practice was essential during the 1960s and 1970s. It allowed for the design of well-organized cities or suburbs. It did not prevent, however, the development of urban pathologies. In order to understand them, other approaches to the role of space in social life had to be developed.

Space as Experience

Functional approaches were specific to the social sciences. They did not offer many possibilities to the cognitive sciences. The situation is different for those who try to analyze space as experience.

Environmental Psychology

The curiosity of psychologists for spatial problems was initially focused on the problems of orientation and place recognition. Their interest changed with the genetic approach developed by Jean Piaget: his problem was to understand the way in which children explored their environment and built behavioral schemes and mental categories out of their experience and inborn capabilities.

The relations between man and environment are mediated through the senses: what are the specific contributions of sight, hearing, smell, touch, taste, and synesthesia to the individual experience of space? Michel Foucault, for instance, was fascinated by the place given to sight by Western civilizations and its role in social control.

Because of its emphasis on experimental methods, mainstream psychology ignored the social dimension of spatial learning and experience. Phenomenologists, Gaston Bachelard or Maurice Merleau-Ponty for instance, brought them back. Environmental psychology introduced the theme of proxemics.

The Psychological, Moral, and Religious Significance of Space

Through phenomenology and proxemics, space started to be conceived as a necessary component of communication systems: hence the contribution of linguistics and semiotics to spatial thinking. Landscapes ceased to be analyzed in a functional perspective. They were conceived of as supports for messages. People experience different forms of connivance with them.

A difference exists between analytical and symbolic communication: in the first case, the problem is to transfer complex sets of information from individuals to individuals; in the second one, it is to stir simultaneously many persons through a unique and short message. Symbolism appears in this way as a tool for mastering distance: hence the interest of geographers for this form of communication.

Space has other social meanings. Normative thinking relies on perspectives from the outside: people have to imagine 'Beyonds,' either within beings or things (when the way of immanence is chosen) or outside them, generally in another world (when the way of transcendence is selected). These choices are important since they introduce a qualitative differentiation of space: places where the Beyonds touch the surface of our world are loaded with sacredness, in contrast to the surrounding profane areas. The building of Utopias, the beliefs in the Golden Age, or in a Land without Evil are ways to use history or terrestrial space to build other types of Beyonds. The dreams they nurture are important in the shaping of rural or urban areas.

The new approaches to geography developed since the 1970s incorporate this interest in the human experience of space.

Social Experience as a Localized Experience

People cannot develop an experience of society outside specific places. The *Time Geography* developed by Torstein Hägerstrand stresses the fundamental diversity of spatial and social experiences developed by people along their life trajectories: it means that social experiences differ according to persons. In the field of communication, for instance, people participate in different intersubjectivity circles depending on the places they live in or had lived.

Such an observation is fundamental for all the social sciences: it reminds that societies, cultures, polities, languages do not exist in a social realm located out of space. They differ from place to place, because of the existence of *locales*, as expressed by Anthony Giddens. The social sciences of today can no more ignore spatial thinking: it is one of the main lessons of the postmodernist epistemological revolution.

The Spatial Turn in the Social Sciences

In the 1970s, many social scientists became dissatisfied with the prevailing conceptions of society and its surroundings. They criticized the static dimension inbuilt in structural theory and its elimination of human agency. They wished to better understand the way social space was built. They deplored the lack of interest in the natural dimension of human environments: hence the development of approaches more open to the spatial dimension of social realities.

The Structurationist Approach

How to give room to human agency? Structural theory envisioned societies as closed and coherent systems: it explained

their organization and functioning, but ignored human initiatives. History was rubbed out. Since the structures upon which emphasis was put were mainly social or economic, space was also eliminated.

Structuralism was built as a one-level theory. Structurationism was conceived as a two-level one: structures remained important for understanding the way social systems function at a given time, but human agency, which was analyzed at another scale, was able to modify the equilibrium of forces, which characterized them. It eventually was responsible for the rise of new structures, which reintroduced the time dimension into social explanation.

Anthony Giddens was interested in Hägerstrand's time geography, since it showed that society never exists as an overarching reality. It is made of a plurality of places. Things, which happen in them, are sometimes linked together. Societies are built as aggregates of *locales* where events are shaped by similar institutions and patterns of behavior. In this way, space was reintroduced into social approaches. The influence of Giddens' sociology was strong in the English-speaking countries.

The Production of Space and Postmodernity

Henri Lefebvre was a Marxist. As a sociologist, he had a keen interest in the specificities of rural and urban areas and was dissatisfied with the lack of interest of the French Communist Party in these problems. For him, Marx's principles of social and economic interpretation were right, but they were developed in another time. They have to be adapted to contemporary situations.

Nature has been transformed by human beings since their first appearance on Earth, but many of its aspects were preserved in traditional societies. With today's overall urbanization, the situation deeply changed. Men are creating a second nature. They are producing the space in which they live.

Fredric Jameson accepted Lefebvre's main conclusions. For him, postmodernity differed from modernity by the growing emphasis it put on spatial problems, and its lesser interest in history.

Environment and Society

The third component of the move back to space grew from the new concern with nature and environment preservation. Human beings do not exist in the ether. They are living organisms. They are part and parcel of nature. Their fate is linked with that of the Earth. With the growing human population and its increased consumption patterns, the pressure on natural environments is higher than ever. Many local or regional environments have lost their resilience, and global imbalances are threatening the future of nature and humanity.

Hence the necessity to pay more attention to the corporeal dimension of human beings, the way they insert in natural settings and their carbon footprint. Space ceases to be conceived of as a neutral support or an obstacle to movement: it becomes a living reality, which has to be preserved if humanity wishes to survive.

During the last 40 years, the interest of social sciences in space has considerably grown. This movement has three components: the first stresses the role of communication in the structuration of social life; the second focuses on the way societies generate the space in which they evolve; and in the third, space is the living environment, which ensures every organism – the human ones in particular – with the elements, air, water, nutrients they need.

Spatial–Temporal Modeling

Emilio Casetti, Ohio State University, Columbus, OH, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Spatial–temporal Models (STMs) formalize the variation of phenomena over time and across space. In the last 20 plus years, the scholarly trends most relevant to STMs have been the growth in importance, relevance, and reach of spatial econometrics, of panel econometrics, and of spatial panel econometrics. In response to these trends, four of the six core sections of this article define and illustrate by examples the following classes: cross-sectional STMs, cross-sectional STMs with spatial effects, panel STMs, and panel STMs with spatial effects. These core sections are preceded by an 'atypical STMs' section and are followed by a section dealing with the 'construction of STMs.' The conclusion touches upon a number of trends that are having an impact on the evolution of spatial–temporal modeling.

Introduction

Spatial–temporal models (STMs) formalize the variation of phenomena over time and across space. A model qualifies as an STM if at least some of its variables are spatially and temporally referenced. Spatial–temporal referencing means that the values of these variables are linked to points or intervals in time and simultaneously, to entities in geographical space such as points, areal units, or arcs or nodes of a network. STMs may also include purely spatial and/or purely temporal variables. Examples of purely spatial variables are distances, directions, spatial coordinates, and spatial dummies. Examples of purely temporal variables are time and functions of time, dummies associated with time intervals, and points in time.

STMs are primarily concerned with three classes of phenomena: spatial flows, spatial diffusion, and spatial–temporal change. The last of the three includes spatial variation of growth rates (for instance, of product per capita), qualitative spatial change (for instance, in land use), and change in spatial distributions (for instance, of crime events or of settlements). A systematic introduction to the spatial–temporal modeling of several classes of substantive phenomena can be found in Haggett et al. (1977).

In the social sciences, much of the conceptual work that precedes or is intertwined with mathematical modeling is based on notions from system theory. Books dealing with the nexus between spatial–temporal modeling and spatial systems include those by Huggett (1980), Klassen et al. (1979), and Banks (1994). STMs figure prominently in the edited collections by Anselin and Florax (1995), Fischer and Getis (1997), Griffith and Haining (1986), Wrigley (1979), as well as Fischer and Getis (2010).

In the last 20 plus years, the scholarly trends most relevant to STMs have been the growth in importance, relevance, and reach of spatial econometrics, panel econometrics, and spatial panel econometrics. In response to these trends, four of the six core sections of this article define and illustrate the following 'classes': cross-sectional STMs, cross-sectional STMs with spatial effects, panel STMs, and panel STMs with spatial effects. These core sections are preceded by an 'atypical STMs' section and are followed by a section dealing with the 'construction of STMs.'

Atypical STMs

The term atypical STMs is used here for models that are spatial–temporal, but do not fit precisely enough in any of the four classes of STMs discussed in the following four sections.

The example of atypical STM discussed in this section is from a paper by Casetti (2003). The paper concerns a pattern of international power dynamics that historically played an important role in the rise and fall of major powers. This pattern consists in the early attainment of power supremacy by comparatively small countries that developed earlier and subsequently lost their status to larger countries that developed later. Cases in point are the staggered rise in power of the United Kingdom, France, Germany, Italy, and Japan, and their subsequent loss of status to the United States and the USSR.

The STMs that formalize this dynamic are based on the following propositions:

- A country's aggregate product is an index of its power.
- A country's product per capita is an index of its development level.
- During development, the percentage rate of growth of product per capita and of population tends to increase at first and then to decline.
- Development latecomers tend to experience greater rates of growth of product per capita and greater rates of growth of population than development pioneers did at comparative development levels.

To produce the power STMs, some notation and definitions have to be established. Let Q, Y, and P indicate a country's aggregate product, product per capita, and population, respectively. Q is also a measure of power. Let

$$q = \ln(Q) \quad [1]$$

$$y = \ln(Y) \quad [2]$$

$$p = \ln(P) \quad [3]$$

Apostrophe superscripts indicate the derivatives of the superscripted variables with respect to time, so that

$$y' = \frac{\mathrm{d}y}{\mathrm{d}t} = \frac{Y'}{Y} = \frac{1}{Y}\frac{\mathrm{d}Y}{\mathrm{d}t} \quad [4]$$

 http://dx.doi.org/10.1016/B978-0-08-097086-8.72066-6

$$p' = \frac{\mathrm{d}p}{\mathrm{d}t} = \frac{P'}{P} = \frac{1}{P}\frac{\mathrm{d}P}{\mathrm{d}t} \quad [5]$$

$$q' = \frac{\mathrm{d}q}{\mathrm{d}t} = \frac{Q'}{Q} = \frac{1}{Q}\frac{\mathrm{d}Q}{\mathrm{d}t} \quad [6]$$

The y', p', and q' are instantaneous percentage rates of change of a country's aggregate product, product per capita, and population, respectively. By definition

$$Q = Y * P \quad [7]$$

$$q = y + p \quad [8]$$

$$q' = y' + p' \quad [9]$$

The power equations are [10] and [11]. The ts in these equations stand for time.

$$y' = \alpha_0 + \alpha_1 y + \alpha_2 y^2 + \alpha_3 t + \varepsilon_y \quad [10]$$

$$p' = \beta_0 + \beta_1 y + \beta_2 y^2 + \beta_3 t + \varepsilon_p \quad [11]$$

Given a sample of countries, and for each of these countries given the values of y', p', y, y^2, and t, Eqns [10] and [11] can be estimated, and after a few manipulations, the value of the measure of power Q can be obtained for any or all the countries in the sample, and for any value of t.

Cross-Sectional STMs

Cross-sectional STMs are models with spatially referenced rates of change over time as dependent variables, and in which at least some of the independent variables are spatial or spatially referenced. Cross-sectional STMs can be found everywhere in the social sciences. For instance, the cross-sectional STMs in which the dependent variable is the rate of change of variables such as income, unemployment, population, welfare rolls, and crime rates, for countries, counties, or regions, and in which the independent variables include indices of relevant characteristics of these geographical entities are indeed common. Also very common are the models in which rates of change are functions of distances or of spatial coordinates.

Cross-sectional STMs have had a strong presence in the empirical literature on the determinants of economic growth. A specific 'case' is the regression models in Barro (1991, 1997). They were estimated using a sample of 114 countries, had growth rates of gross domestic product (GDP) per capita as dependent variables, and GDP per capita, male schooling, fertility rates, democracy indices, inflation rates, and others as independent variables.

Cross-Sectional STMs with Spatial Effects

Cross-sectional and panel STMs with spatial effects use techniques and concepts from spatial econometrics. For more on spatial econometrics, see Anselin (2001, 2007), LeSage and Pace (2009), and Getis (2010).

The GeoDa program provides users with an exposure to the practicalities of spatial econometrics. Interested readers can download free-of-charge GeoDa and related documentation from the site https://geodacenter.asu.edu.

The following example of cross-sectional STMs with spatial effects draws upon Fingleton (2007), which analyses the relation between changes in wages and levels of wages during 'globalization.'

The data used are wages per worker in 1996 constant prices, for the years 1970 and 2000, and for a sample of 98 countries. The year 1970 is assumed to mark the approximate onset of globalization. Denote by 'w' the wage per worker in 1970, and by 'D' the difference of the wage per worker in 2000 minus the wage per worker in 1970.

The theory reviewed in Fingleton (2007: pp. 394–397) suggests that the wage difference, D, is low at low wage levels; accelerates to a maximum as wage levels rise; and then decelerates with further wage level increases. In other words, the theory suggests a quadratic model

$$\begin{aligned} D &= \alpha w^2 + \beta w + \gamma + \varepsilon \\ \varepsilon &\sim N(0, \sigma^2) \end{aligned} \quad [12]$$

Here and hereafter, the Greek letters indicate parameters, while their Roman counterparts stand for estimated parameters. Upon estimation, eqn [12] portrays a parabola with a maximum if the estimated parameters a and b are significant, and if $a < 0$ and $b > 0$. The ordinary least squares estimates of model [12] parameters given in Fingleton (2007: p. 399, Table 16.1) show that b is significant and greater than zero and that a is smaller than zero but is not significant. Fingleton (2007: p. 399) comments that "a quadratic function does not seem to describe the relation between … [D and w]." Also, on the basis of a Moran's I test, he remarks that "There is evidence of very significant residual spatial autocorrelation." In other words, the estimated quadratic is not congruent with theory.

The line of thought that Fingleton follows to render the model congruent with theory can be summarized in three propositions:

- Globalization is associated with a growing interdependence of national economies.
- These interdependencies translate in a plurality of 'shocks' that every country receives from its 'neighbors.'
- This interdependence of economies can be explicitly modeled via the spatial error model (Fingleton, 2007: p. 398).

On the basis of these propositions, eqn [12] was converted into its spatial error counterpart below:

$$\begin{aligned} D &= \alpha w^2 + \beta w + \gamma + u \\ u &= \rho W u + \varepsilon \\ \varepsilon &\sim N(0, \sigma^2) \end{aligned} \quad [13]$$

To estimate eqn [13], a specification of the spatial weight matrix W is required. W is a 98×98 matrix with its rows and-columns linked to the sample's countries. Indicate by W_{ij} the element of W at the intersection of the ith row and jth column. Equation [13]'s Maximum Likelihood (ML) parameter estimates reported in Fingleton (2007: p. 400, Table 16.2, column 3) is based on the following specification of W: $W_{ij} = 0$ if $d_{ij} > 10\,000$ miles; $W_{ij} = 1/d_{ij}$ if $d_{ij} < 10\,000$ miles, where d_{ij} is the great circle distance between the capital cities of countries i and j.

The ML estimated parameters of w and w^2 are both significant and are, respectively, greater and lesser than zero, as theory suggested that they should be. Actually, Fingleton experimented with several weight matrices, some 'not row standardized' as the one described above, and others 'row standardized,' and in all cases they produced parameter estimates consistent with theory. The message emanating from Fingleton's paper is clear: the spatial effects augmentation of an inadequate model may render it adequate. Note that here both the original model and its augmentation are based on solid theoretical foundations.

Panel STMs

In the past 20 plus years, spatial temporal modeling based on panel data has seen considerable growth. Evidence of this growth includes the number of panel STMs books and papers published in recent years, the variety of scientific fields in which panel STMs have been used, and the proliferation of panel STM linkages with other branches of econometrics. Prominent among these linkages is the one between panel STMs and spatial econometrics.

The fast spread of panel STMs has been credited to factors that include the following:

- Spatial panel data have become increasing available.
- The panel STMs proved effective in investigating issues that cannot be addressed by either cross-sectional or time series analyses alone (Hsiao, 2003; Baltagi, 2005).
- Panel STMs tend to use a larger number of data points, which increases the degrees of freedom and reduces collinearity (Hsiao, 2003: pp. 1–2).
- The panel literature dealing with, or related to, 'fixed effects' and 'random effects' proved capable of controlling the heterogeneity resulting from the absence of unavailable or unknown variables (Baltagi, 2007; Arellano, 2003: pp. 7–29; Baltagi, 2005: pp. 4–5 and 11–47).

The Baltagi and Pinnoi (1995) paper on the relationship between public infrastructural investments and private sector productivity will be used to illustrate an application of panel STMs. The panel data sets are time series of cross-sections. Here, each cross-section is made of 48 data vectors, each linked to one of the 48 contiguous US states. The panel data consists of 17 cross-sections, one for each of the 17 years in the time interval 1970–86. Consequently, the total number of data vectors is 816.

Each data vector contains the state name and the year to which the vector is linked, plus the values of eight variables for that state and year. The variables and their names are defined as follows:

1. Y = Gross state product
2. K = Private capital stock
3. L = Labor inputs (employment in nonagricultural pay rolls)
4. U = State unemployment rate
5. KH = Value of public capital in highways and streets
6. KW = Value of public capital in water and sewers facilities
7. KO = Value of public capital in other (public buildings and structures)
8. KG = Value of public capital in KH + KW + KO

All variables except U are in natural logarithms. The state unemployment rate, U, is entered in all models in order to attenuate the effects of temporal trends and of the business cycle. Y is the dependent variable in all the models in the paper. Let [14] and [15] denote two linear regression models defined by their dependent and independent variables:

$$Y = f(K, L, \mathrm{KG}, U) \qquad [14]$$

$$Y = g(K, L, \mathrm{KH}, \mathrm{KW}, \mathrm{KO}, U) \qquad [15]$$

These regression models are designed to determine whether the aggregate public capital KG in [14], or all its components KH, KW, KO in [15], contribute(s) significantly to the state's product. Both equations were estimated by the 'within estimator' of the 'fixed effects model' and by the 'between estimator' of the 'random effects model.' These models and estimators are discussed in chapters 2 and 3 of Baltagi (2005).

The estimates of [14] and [15] by 'between' regression can be found in columns 5 and 6 of Table 1 in Baltagi and Pinnoi (1995: p. 354), and the estimates of [14] and [15] by 'within' regression can be found in the same table in columns 8 and 9.

The interpretations of these four results are based on the well-established notion that 'between' and 'within' regressions indicate, respectively, long-run and short-run dynamics. For a review of this notion, see Baltagi (2005: pp. 200–205). The results of these four estimated regressions can be summarized as follows:

- The effects of the aggregate public capital, KG, in the short term are negative and nonsignificant, and in the long term are positive and significant.
- The effect of the three capital stocks, KH, KW, and KO, are not uniform. Namely, the effects of KH and KW are positive and significant in the short and long run. Instead, the effects of KO are negative and significant in the short run, and positive but not significant in the long run.
- The main conclusion is that the regression results from the [15] model give better insights into the complex interactions that shape the short-run and long-run effects of public investments on the private sector.

For a deeper analysis of these interesting results, see Baltagi and Pinnoi (1995: p. 355). Here, it will suffice to point out that their paper demonstrates very effectively how interesting and substantively important are the long-run short-run analyses that panel econometrics makes possible.

Panel STMs with Spatial Effects

The paper by Moreno and Lopez-Bazo (2007) will be used to illustrate an application of panel STMs with spatial effects. The two models in this demonstration are concerned with the effects of public investments on private sector productivity. However, the first model falls within the scope of panel econometrics, while the second is an implementation of the interface of panel and spatial econometrics.

In connection with model [16] the reader may find it useful to consult Baltagi (2005) and/or Hsiao (2003). In connection with model [17], in addition to these texts the

papers by Anselin et al. (2008) and Elhorst (2010) can provide a useful background.

The data panel used in this illustration consists of a time series of 17 cross-sections. Each cross-section is made of 50 data vectors associated with 50 Spanish provinces. The 17 cross-sections are linked to 2-year partitions of the 1975–97 time interval. Clearly the data vectors are spatially and temporally referenced, and are 850 in number.

Each data vector contains the values of seven variables. The variables are in natural logarithms, and are defined as follows:

1. Y = Manufacturing output
2. K = Capital inputs
3. L = Labor inputs
4. KL = Public sector 'local' capital stocks
5. KT = Public sector 'transportation' capital stocks
6. WKL = 'Local' spillovers
7. WKT = 'Transportation' spillovers

KL stands for capital stocks that produce effects locally, and KT stands for transportation capital stocks that produce effects both inside and outside the province in which they were created. A province's spillovers WKL and WKT are averages of the KL and KT values of the province's neighbors.

In terms of spillovers, infrastructural investments can produce effects directly in the province in which they are made, and indirectly as averages of the KL and KT values of this province's neighbors. Note that spillovers qualify as an example of the spatial econometrics' spatial lag variables.

The models reported below are discussed in Moreno and Lopez-Bazo (2007: p. 53). These models are

$$Y_{\mathrm{it}} = \beta_0 + \beta_1 K_{\mathrm{it}} + \beta_2 L_{\mathrm{it}} + \beta_3 \mathrm{KL}_{\mathrm{it}} + \beta_4 \mathrm{KT}_{\mathrm{it}} + m_{\mathrm{i}} + n_{\mathrm{t}} + \varepsilon_{\mathrm{it}} \quad [16]$$

$$\begin{aligned} Y_{\mathrm{it}} &= \beta_0 + \beta_1 K_{\mathrm{it}} + \beta_2 L_{\mathrm{it}} + \beta_3 \mathrm{KL}_{\mathrm{it}} \\ &= \beta_4 \mathrm{KT}_{\mathrm{it}} + b_5 \mathrm{WKL}_{\mathrm{it}} + \beta_6 \mathrm{WKT}_{\mathrm{it}} \\ &\quad + m_{\mathrm{i}} + n_{\mathrm{t}} + \varepsilon_{\mathrm{it}} \end{aligned} \quad [17]$$

The m_{i} and n_{t} terms are needed to include both region-specific effects and year-specific effects in the specification of the error term. The results from the estimation of models [16] and [17] can be found in Moreno and Lopez-Bazo (2007: p. 58, Table 2, columns 1 and 2).

In model [16], the estimated parameter of KL is significant, while the estimated parameter of KT is not. In model [17], the spillovers WKL and WKT have effects that are interesting and complex. First, the effects of KT in model [17] are stronger than in model [16], which suggests that its impact was underestimated in model [16]. Second, the WKL spillover is not significant, thus confirming that the effects of KL are local only. Third, the effect of WKT is significant and negative.

This third result is explained in Moreno and Lopez-Bazo (2007: p. 59) as the result of 'factor migration from regions with poor transport infrastructure endowment to regions with good endowments.' In other words, WKT reflects beneficial inflows of resources and skilled personnel into some provinces and damaging outflows of resources from other provinces. The negative and significant estimate of WKT's parameter indicates that in the balance the damages outweigh the benefits. This shows that here the integration of spatial econometrics with panel econometrics yields results that would have not been possible to obtain from either alone.

Constructing STMs

In many cases, STMs in the social sciences have been imported from non–social science disciplines. For instance, some of the diffusion models in geography and economics originated in physics and engineering (Banks, 1994). In general, the analogies between different phenomena may trigger interdisciplinary transfers of methodologies and models. The notions of systems and system dynamics and the schools of thought linked to them have played a major role in the construction of classes of STMs based on cross-disciplinary analogies.

However, in many circumstances the need may arise to construct STMs from purely spatial or purely temporal models, or to extend existing STMs to encompass relevant contexts that are outside their original scope. An approach to the incremental construction of mathematical models that can be easily applied to building STMs is the 'expansion method' (Casetti, 1997). In a nutshell, the expansion method involves widening the scope of a simpler 'initial model' by redefining some or all of its parameters into functions of expansion variables or variates that index substantively relevant contexts of the initial model. The terminal model thus produced encompasses both the initial model and a specification of its contextual variation.

To demonstrate the operation of the method, let us discuss its application to adding a time dimension to a purely spatial model of urban population densities. This demonstration is based on a variant of the model presented in Casetti (1973). The urban studies literature has identified two spatial patterns of urban population densities that are often referred to as density cones and density craters. In the cones, population densities decline exponentially with distance from city centers. Urban population densities that increase at first and then decline as the distance from the city center increases characterize density craters.

Let D, s, and ε denote, respectively, the natural logarithm of urban population density, distance from a city center, and an error term. Let

$$D = \alpha_0 + \alpha_1 s + \alpha_2 s^2 + \varepsilon \quad [18]$$

be an initial model subsuming both a density cone and a density crater as special cases. In fact, for $\alpha_1 < 0$ and $\alpha_2 = 0$ this model corresponds to a density cone, while for $\alpha_1 > 0$ and $\alpha_2 < 0$ it yields a density crater.

The literature has also identified distinctive patterns of temporal change in these spatial trends. They include the rising and flattening of the density cones, the widening of the density craters, and the gradual transformation of cones into craters. In order to extend the initial purely spatial model [18] so that it will encompass the spatial–temporal trends recognized in the literature, the α parameters are expanded by the stochastic expansion equations

$$\alpha_i = \alpha_{i0} + \alpha_{i1} t + \theta_i, \quad i = 0, 1, 2 \quad [19]$$

where the θs are error terms. The terminal model

$$D = \alpha_{00} + \alpha_{01}t + \alpha_{10}s + \alpha_{11}st + \alpha_{20}s^2 + \alpha_{21}s^2t + u \quad [20]$$

$$u = \varepsilon + \theta_0 + \theta_1 s + \theta_2 s^2$$

is obtained by replacing the right-hand sides of the expansion equations for the αs in the initial model. Upon estimation, this terminal model can be used to test for the occurrence of specific spatial–temporal trends and to portray these trends if they occur.

The model in this example is intended for estimation and testing statistical hypotheses. It should be noted though that the expansion method can be used to construct STMs of any kind. Any model that has parameters can be expanded, irrespective of whether it is deterministic, stochastic, or mixed, and irrespective of whether it is intended for solving, estimating, or optimizing.

Concluding Comments

Most STMs in the social sciences came into existence in the past 70-odd years, and have been influenced or shaped by trends that kept altering the landscape of the quantitative analytical social sciences during this time horizon. The comments that follow highlight some such trends and influences.

Mathematical models in general, and STMs in particular, have been acquiring an important role in government and private sector activities as aids to decision making, to planning, to policy development and evaluation, and for forecasting. In the process, they have been driven to address the complexities of the real world to an ever-increasing degree. The tendency toward more complex models is especially apparent in all kinds of STMs. Their proliferation is a reflection of their practical usefulness. The movement toward the computational counterparts of STMs that originated as purely mathematical formalisms is another aspect of these tendencies.

Increasingly complex STMs have also played an important role in the precise articulation of theories and conceptual frameworks that are important components of the social sciences. In the more theoretical applications, this growing complexity has been intertwined with conceptual and technical advances imported from mathematics and a variety of sciences. STMs related to nonlinear dynamics, and ones centering on optimal control techniques, are cases in point.

The entire evolution of STMs and of mathematical modeling at large has been permeated by the growth of stochastic modeling and by the penetration of stochastic elements into models born deterministic. For instance, deterministic cross-sectional STMs have been converted into 'mixed' or stochastic models by the addition of stochastic errors and/or of temporally or spatially autoregressive terms. An adequate stochastic specification and its attendant statistical econometric testing has increasingly become a must for empirical analyses to be credible.

Abstract

Clusters of specialized firms are now coming to be recognized as an important level of integration and organization in successful industrial economies. Such clusters, among which are industrial districts, were prominent in nineteenth-century European industrial development (in Italy, Britain, and Germany) and in the United States, and then in Japan, and are now viewed as being central to successful industrial development in the twenty-first century in China and India, where they are specifically promoted through ad hoc policies. In designating special economic areas, such as geographic clusters of firms or special economic zones (SEZs), national and regional authorities aim to attract and stimulate economic activities in specific, bounded areas of the country, where business-friendly rules can apply. After presenting the rationale and main features of SEZs, the article illustrates the experience of China, and in particular Guangdong Province and the Pearl River Delta, where SEZs based on Shenzhen and other urban centers have played a prominent role. A careful analysis of the policies adopted in the country to kick off and manage the transition process highlights a central concern of the government to manage the spatial patterns of industrial development. Specific tools have been developed in order to shape the geography of industry: cluster promotion has been pursued while also managing a number of SEZs with the specific aim to concentrate the early stages of industrial development in confined areas, learning from the prior experience of industrial districts in Europe, the United States, and Japan. In China, and especially in Guangdong, the development of SEZs and the promotion of clusters of firms have gone hand in hand to achieve long-term industrial development objectives.

Introduction

In spite of its prominence in neoclassical economic literature, 'the firm' is not the only institution relevant to production processes. Classical scholars such as Alfred Marshall in the nineteenth century understood clearly that what happens outside the firm, through external as well as internal economies, could be decisive to industrial success. Marshalls, pioneering studies of industrial districts in Britain and Germany have been taken up in the twentieth century in Italy by Becattini (1989), and in general terms by Coase (1937) and Williamson (1975), to cite just two of the distinguished authors who have tackled this subject. Supra-firm organizations emerged since the first English industrial revolution (Marshall, 1890/1920/1972), and they can hardly be considered exceptions. Clusters of firms, industrial districts, networks of companies, and business groups are all common manifestations of such supra-firm organizations.

Although each supra-firm structure has its own peculiarities, they also share some common features. In a sense, they all deal with the costs associated with market transactions without necessarily bearing the diseconomies inherent in large integrated organizations. Moreover, they all refer to a common idea that a higher degree of (collective) efficiency can be reached by independent single firms thanks to the exploitation of economies that these supra-firm organizations bring in their wake. Yet they can differ because of varying degrees of social embedding of the actors involved or because of the presence (or absence) of explicit collective actions.

In this scenario, the spatial dimension is an important additional distinguishing factor. In the case of industrial districts – or, more generally, in the case of clusters of specialized firms – spatial proximity allows firms to exploit Marshallian externalities (a constant market for skills, local specialized suppliers of goods and services, and access to specialized knowledge) as well as other external economies arising from explicit collective actions of neighboring firms.

For these reasons, development policies have tried to promote agglomerations of specialized firms in particular localities. Examples are the many European initiatives in favor of cluster development and consolidation (tracked, e.g., by the European Cluster Observatory, www.clusterobservatory.eu); the experience of the British biotechnology industry of Cambridge (Waters and Lawton-Smith, 2008); the interesting story of the high-tech pole of Sophie Antipolis in France; the 'one-city one-product' Chinese specialized towns (STs); the Brazilian shoe cluster in Synos Valley; the clothing cluster in Nairobi; the electronic engineering cluster in Bangalore, India; and many more.

There are three basic intuitive ideas behind these diffused kinds of policy interventions. First, clusters might offer unique advantages to firms because of geographical proximity within a specific area. Second, such proximity might also encourage important profitable collaborations among firms. These advantages make clusters 'special territories' for firms. Thus, policies in favor of cluster development can also be read as a way of offering firms a special site (zone, area, etc.) with unique favorable conditions. Finally, these territories are also special not only because in these sites firms cluster together but also because a variety of other relevant actors (public and private institutions, universities, laboratories, government agencies, etc.) agglomerate and firms are enabled to specialize (Mathews, 2012).

In this scenario, policies in favor of the establishment of special economic zones (SEZs) – especially in the form of high-tech development areas or dedicated industrial parks – can be understood from a similar perspective. They in fact display a strong geographical component where national and regional

authorities aim to attract and stimulate economic activities in specific, bounded areas of the territory. The aims to be achieved through such instruments are many, as will be briefly described in the section SEZs: Rationale and Organization. Here we wish to emphasize the implicit idea of these kinds of policies: attracting firms in a specific location will also create favorable conditions for the emergence of the above-illustrated cluster economies. Given that these economies are advantages that are available to firms localized in a specific area and usually specialized in the same economic sector (or a highly related one), it is not unusual to find SEZs or industrial parks that identify specific priority sectors.

For instance, in the case of Shenzhen, China, which is reviewed in the section Main Features for Successful (and Unsuccessful) SEZs, the concentration in the city of firms operating in the electronic sector, favored by the special privileges granted by SEZ status, has undoubtedly facilitated the flourishing of common services, the attraction of specialized workforce, and other sector-specific advantages that have multiplied the effects of the SEZ establishment per se. This setting has then reasonably encouraged joint actions and collaborations among a variety of relevant and specific actors, offering to the new clustered local economy unique competitive advantages.

The more general experience of China, and in particular that of Guangdong Province, seems to be particularly relevant in this context. The exceptional rate of growth that, starting from Guangdong Province, has characterized the whole country (Di Tommaso et al., 2012) calls for attention to the specific policy tools adopted to kick off and govern the transition process started at the end of the 1970s. A careful analysis of such policies highlights a main concern of the government toward the geography of production and the spatial patterns of industrial development. Specific tools throughout the different stages of growth have been developed in order to shape the geography of industry: cluster promotion has been pursued with ad hoc instruments while also managing a number of SEZs with the specific aim to concentrate the early stages of industrial development in certain designated areas. In China, and in Guangdong more than in other places, the development of SEZs and the promotion of clusters of firms have gone hand in hand in order to achieve long-term industrial development objectives.

SEZs: Rationale and Organization

The rationale behind SEZ establishment can be traced back to the eighteenth century, with free zones in Gibraltar (1704), Singapore (1819), Hong Kong (1848), Hamburg (1888), and Copenhagen (1891) (World Bank (WB), 2008). However, the first 'modern' SEZ was established in Ireland in 1959, followed by SEZs in lower-income countries, among them the Dominican Republic, India, and Taiwan. In the last 30 years, SEZs have become an increasingly important instrument of export promotion and economic development in both industrialized and industrializing countries. According to a database developed by the International Labour Organization (ILO), in 1975 there were 79 zones in 25 countries (all government owned), which grew to 3500 zones in 130 countries 20 years later (interestingly, more than half of which are private) (WB, 2008).

SEZs can be defined as 'demarcated geographic areas contained within a country's national boundaries where the rules of business are different from those that prevail in the national territory' (Farole, 2011, p. 23). This broad definition encompasses several typologies, which differ according to the kind of granted privileges, target firms, final market of destination, operational rules, and internal organization.

The main ones are the following (WB, 2008):

- Free trade zones (FTZs) (or commercial free zones). These are delimited duty-free areas offering all the facilities for trade, transshipment, and reexport. Usually in these areas, there are weaker customs controls.
- Export processing zones (EPZs). These industrial estates are for the location of export-oriented enterprises. They do not necessarily offer the same tax benefits as FTZs, but they do offer a functional advantage, especially for foreign exporters. There are also hybrid EPZs, divided into a separate area for export-oriented firms and a zone open to all industries independent of their export orientation. Normally, EPZs require that a specific percentage of production is exported. EPZs are a type of SEZ that has been studied more in the literature, and sometimes the two terms are used synonymously.
- Freeports. These are larger areas hosting all kinds of activities, from tourism to retail sales, and providing a wide set of incentives. For this reason, these areas tend to be more integrated in the host economy.
- Industrial parks (or enterprise zones or industrial development zones). These areas have the aim of revitalizing relatively underdeveloped urban or rural areas. Here the free trade component is less relevant, while special attention is given to infrastructures and services for industries. They are usually used in developed countries.
- Export processing factories (EPFs) (sometimes called enterprise zones or single factories). These are a case of ad hoc incentives granted to a specific firm. In this case, the firm operating under the privileges of the SEZ is not physically located within an industrial estate, but the boundaries of the zone coincide with the boundaries of the factory.
- Other specialized zones such as science and technology parks, logistic parks, airport-based zones, and so on.

The usual privileges from which firms benefit in SEZs are as follows (Farole and Akinci, 2011):

1. tax exemption and tax holiday periods, ranging normally from 5 to 20 years, although there are cases, such as Jamaica, where the tax holiday period is unlimited;
2. unlimited, duty-free imports of raw materials, equipment, machinery, and intermediate goods for the production of exports;
3. duty-free on exports;
4. liberal foreign exchange policies;
5. less governmental red tape and more flexibility with labor laws for the firms in the zones than for those outside;
6. above-average communication services and infrastructure such as roads, power supplies, and transport facilities together with, in some cases, subsidized utilities and rental rates;

7. no limitation on foreign ownership of the firms or on the repatriation of profits in most cases;
8. other incentives such as value-added tax (VAT) exemption and training subsidies.

The role assigned to SEZs differs from country to country. For instance, in industrializing economies such as South Korea, Malaysia, and Thailand, SEZs were established as part of a policy shift from an inward- to an outward-oriented economic policy. In these cases, SEZs, and in particular EPZs, were meant to evolve and integrate with the domestic economy until they would no longer be enclaves.

According to many theoretical contributions, these areas offer a liberal and free trade environment, while in many cases (first of all in China, which will be described in the section Main Features for Successful (and Unsuccessful) SEZs, but also elsewhere) SEZs have been a way to manage the transition, opening only specific areas while keeping the rest of the country closed. In other countries, such as the Philippines and Indonesia, SEZs were introduced as 'safety valves' in a context of inward-oriented economic policy in order to create at least some areas free from distortions. In this case, the appealing feature of SEZs is that the host country can enjoy several benefits in terms of job creation, improvement of the balance of payments, and absorption of technology and at the same time it can keep the domestic industry protected from foreign competition. More recently, SEZs have been used by countries where foreign direct investment (FDI) was particularly low. In these cases, they have been an instrument to compete with neighboring countries offering better incentives to foreign investors.

To summarize, and in line with the relevant literature (Warr, 1990; Johansson and Nilsson, 1997, Farole and Akinci, 2011; WB, 2008), the main objectives of SEZs have traditionally included:

- to provide foreign exchange earnings by promoting exports;
- to create jobs, in order to reduce unemployment;
- to attract FDI to the host country;
- to accelerate the industrialization process, thanks in part to desirable spillover effects on the local firms that are incentivized to sell goods and services to zone-based enterprises since these sales are exports and can benefit from export incentives;
- to accompany and support wider economic reform.

Main Features for Successful (and Unsuccessful) SEZs

Given that SEZs have had a variety of different policy goals, the literature has highlighted both successes and failures.

One of the principal challenges for SEZs has been the relationship between foreign companies and local producers (Johansson and Nilsson, 1997). In contemporary markets in both industrialized and industrializing countries, SEZs must be considered as platforms that are able to connect global and local actors. In other words, SEZs have to be 'glocal.' SEZs with only local producers separated from global producers or SEZs with only foreign producers isolated from the local economy could hardly be defined as successful. Effective SEZs are the ones that are able to play a crucial local–global binding role in the name of national and local industrial development policy targets. Multinational enterprises and FDI can – or cannot – exchange with domestic companies located within (or in proximity of) that specific area modern technology, export know-how, ideas, or knowledge on production, marketing, and distribution, thus stimulating and improving local production. One of the major obstacles to local industrial development is, in fact, the lack of 'capacity to package' the technical, marketing, and managerial know-how with domestic and external resources. If SEZ firms succeed in creating sufficient backward links with domestic firms, they can fill this gap (Johansson and Nilsson, 1997). The integration with the local economy is the most important and also the most difficult task for SEZs, and only a few countries have succeeded significantly in this respect.

A potential failure for policies based on the SEZ establishment is also connected to the negative effects that SEZs might have outside their boundaries. The existence of SEZs should not penalize the rest of the companies operating outside. The problem can be severe especially if inside-the-SEZ foreign companies compete (exploiting the advantages of preferential policies) with outside-the-SEZ domestic companies that cannot count on the same advantages. An interesting experience in this respect is that of the so-called equal footing policies (i.e., all the measures aim at granting the same benefits to SEZs' foreign exporting firms and to local exporting firms even if they are located outside the SEZ).

Other factors determining the success or failure of SEZs are indicated by the literature, such as the local economic environment or a good locational choice. Where SEZs are located can make the difference between success and failure. In other words, geography matters for SEZs.

Moreover, successful SEZs offer agglomeration economies that companies located in one specific locality might (or might not) exploit. SEZs are also agglomeration of firms, institutions, and people. Successful SEZs offer advantages connected to spatial proximity. And not only spatial proximity matters, but also specialization does. The international cases show that the more specialized SEZs are, the more likely they are to be successful in the medium to long run. This is probably due to the fact that besides the specific privileges granted by the SEZ establishment, there is also an incremental effect due to the exploitation of the above-mentioned cluster economies.

However, SEZs should be considered successful (or not) with reference to one specific national industrial policy framework. As has commonly been described, SEZs have been free-market and trade-opening tools. And in this field, in many circumstances, SEZs have been successful, playing an important pilot role. However, SEZs have also been an important instrument for governments interested in maintaining a role in guiding national industrial development and structural change. In other words, SEZs should also be evaluated by focusing on other long-run strategic-planning and policy design issues. SEZs not only have been tools for promoting 'free-market islands,' but also, in contrast, have been instruments utilized by interventionist governments involved in industrial issues. In the Chinese experience, it is possible to find both rationales in different historical phases and in different locations (Di Tommaso et al., 2012). In many other countries, the establishment of SEZs

has been functional to industrial policy strategic needs. Very often, and especially in recent times, SEZs have played a dynamic strategic role in responding to continuous changes in global industry. This evolutionary aspect of SEZs has also been underlined by Farole and Akinci (2011), who in their recent report suggest that the proliferation of SEZs has been favored by a globalization process that started in the 1970s, accelerating during the 1990s and 2000s, coupled with an increased fragmentation of manufacturing production leading to 'global production networks.'

Clusters and SEZs: The Case of China

Special Economic Zones: From Experimentation to Growth and Beyond

China's SEZ experience represents a unique case at the world level, where SEZs have been the main tool used to support the opening of the economy. They were designed as 'laboratories' in which to experiment with accelerated economic development and the controlled import of foreign technologies and capital, with the idea of expanding the process to the rest of the country if successful.

In particular, the main aims of the establishment of SEZs in China were (Ota, 2003):

1. To observe and understand capitalism;
2. To test different policies;
3. To acquire capital, modern technologies, and management methods;
4. To accelerate exports;
5. To create local job opportunities, especially for young people;
6. To generate foreign exchange to finance China's import needs;
7. To promote competition among regions;
8. To facilitate the future return process of Hong Kong, Macao, and Taiwan into China, by favoring a graduated reduction of income gaps between these places and mainland areas.

The first step of this process has been the promulgation in 1979 of the 'Law of the People's Republic of China on Chinese-Foreign Joint Ventures,' whose main objective was the attraction of foreign capital to support growth, while keeping control of the process. In the following year, three SEZs were established in Guangdong Province (in Shenzhen, Zhuhai, and Shantou) and one in Fujian Province (Xiamen), all close to strategic sources of foreign capital, Hong Kong (Shenzhen) and Macao (Zhuhai), and facing Taiwan (Shantou and Xiamen) (Ota, 2003). The central government allowed SEZs to make autonomous decisions with regard to relevant aspects for their development (excluding railways, postal and telecommunication services, banking, civil aviation, and national defense). They were encouraged to experiment with policy innovation, being certain that successful initiatives would have been fully recognized. To increase their autonomy and minimize the risks of political interference from the central government, they were purposefully located far from Beijing.

Foreign investors and other economic actors located in these areas benefited from this diverse institutional framework (Di Tommaso et al., 2012). Furthermore, they could count on the availability of a highly skilled labor force, a battalion of low-cost migrant workers coming from the rural areas of the province, and no risks of interference from trade unions.

Probably also because it was the first to be established, Shenzhen is surely the most emblematic case. The central government granted to the local administration a 10-year exemption from the submission of tax revenues to the central and provincial governments and, since 1981, the same political status as the capital. In 1992, the central government also granted it legislative power.

This special status allowed many revolutionary changes in regulation and administration to be tested and tried out. Among these were the selling of state land-use rights, the establishment of personnel system reforms, the abrogation of voucher quotas for food purchases in 1984 (10 years before the rest of China), the opening to foreign banks in 1982, the state-owned enterprises (SOEs) reform in 1986, and the establishment of a stock exchange in 1990 (for a comprehensive overview of the implemented reforms, see Di Tommaso et al., 2012).

This framework has allowed a very rapid growth of the city. In 1979 (i.e., only a year before being transformed into an SEZ), Shenzhen was an agriculture-based village, with an irrelevant contribution to China's GDP (less than 1%) and a per capita GDP below US$90 per year. There were only 20 000 residents with low education levels and poor living standards. The manufacturing sector was practically nonexistent. The only advantage the area had was its proximity to Hong Kong, Macao, and Taiwan and its low resistance to any kind of structural change because of its simple social structure and the absence of internal conflicts. Shenzhen over time demonstrated itself to be one of the fastest growing cities in China, with a yearly growth rate of 15% in 2008. Thirty years after the establishment of the SEZs, in 2010, *Forbes* magazine included Shenzhen among the top five most-crowded cities in the world.

Shenzhen now ranks second after Guangzhou in terms of per capita GDP: in 2009, it amounted to RMB 92 772 (approx. US$13 000). Its industrial output is the highest among all provincial cities (RMB 1541 billion – approx. US$217 billion), and industry accounts for a growing share of GDP formation and GDP growth. Shenzhen sees a huge concentration of activities on high-tech sectors, particularly electronics, which in 2008 accounted for 91% of the total output value of high-tech industries. This can be partly read as a consequence of the fact that at the initial phase of the opening processes, wholly foreign-owned enterprises were authorized only if they exported at least 50% of their output or produced high-tech goods. Therefore, several multinationals operating in technology-intensive sectors have established branches in the prefecture, such as IBM, Intel, Toshiba, Epson, Xerox, and Hitachi (Di Tommaso et al., 2012).

Great efforts have been made toward the reinforcement of the political independence of the area, while at the same time reducing the role played by the government in microeconomics. This has been done by means of the creation, in 2004, of government departments that are independent from national ministries.

As a consequence of the success of the first SEZs, SEZ status was extended to 14 urban coastal centers and to Hainan Island. Guangzhou was declared an 'open coastal city,' and in 1985 the Pearl River Delta was officially designated an 'open economic

region' (along with the Yangtze River Delta and the Golden Triangle Delta) with the aims of obtaining accelerated economic development and of knowing in advance what was happening on the international scene (Barbieri et al., 2012). In 1988, the central government authorized the establishment of two other SEZs – in the Pudong district (Shanghai) and in Hainan, and the latter was at the same time also separated from Guangdong and declared an autonomous province. Accelerated growth has, of course, created several problems that are now visible in Shenzhen. Congestion, traffic, pollution, difficulties with providing services to everyone in an overcrowded area, and so on are all issues with which policy makers are being challenged.

More recently, SEZs have been used by Chinese policy makers to help rebalance the development of the country. While the tool of 'special zones' remains relevant, it is employed for new targets and long-term objectives that place renewed emphasis on the cluster promotion aspects of policy.

An interesting example in this scenario is the Double Relocation Policy, launched in 2008 by Guangdong. The aim was to relocate the labor-intensive, resource-consuming manufacturing industries from the central area to less developed areas and the workforce from the agricultural sector to the secondary and tertiary sectors.

In order for the relocation to take place, the plan foresaw the ad hoc creation of 'industry-transfer demonstration parks,' aimed at hosting the sectors moving from their original locations. The main requirement is that all industries accepted by these parks be developed into one or more clusters, with one dominant sector and several supporting sectors (Wang and Yue, 2010, p. 194). By January 2011, the parks alone have absorbed about 426 000 people, more than 60% of which are coming from Guangdong. Firms located in the new industrial parks are encouraged to employ local people and the government will also provide free polytechnic education for the most rural poor (Di Tommaso et al., 2012).

Clusters: The Case of Specialized Towns in Guangdong Province

In the study of supra-firm structures, the Chinese case is particularly interesting not only for the peculiar use of SEZs that has just been described, but also because they have been used in tight connection with other policy instruments, such as in the case of Guangdong's STs (Di Tommaso et al., 2009).

Guangdong Province is among the most developed parts of China. In this area, the government played a strong role in industrial development, with great attention placed on how to influence the location of firms in the province. The aims were to manage the incredibly fast – and often disordered – development of some of its territories (with double-digit yearly growth figures since the beginning of the 1980s) while encouraging the development of the other, more backward areas. In particular, Guangdong government planners thought that favoring the agglomeration of specialized firms in a few specific locations could help attain the two aforesaid goals and more generally encourage industrial development, competitiveness, innovation, and technological advancement (Di Tommaso et al., 2012).

It has to be said that, similar to what happened in the rest of the world, in Guangdong Province the formation of several agglomerations of (similar or complementary) firms has been a spontaneous process. What makes Guangdong's (and China's) experience unique is the decision of policy makers to accelerate and guide this process by means of specific policy measures.

The origin of such measures dates back to the second half of the 1980s, when the Chinese government introduced the Spark Programme (Department of Science and Technology of Guangdong Government (DSTGG), 2003; Barbieri et al., 2010). The aim was to raise the technological innovation capacity in several rural areas of the country, particularly by establishing investment areas known as 'spark technology investment zones,' where firms could utilize subsidized funds coming from government and banks. These investment zones represent the seeds from which several Guangdong STs originated. In many cases, in fact, each area tended to specialize in a specific sector (one city, one product). Given that the town was the prevailing administrative unit among these agglomerations, they were called 'specialized towns' (Di Tommaso and Rubini, 2006; Di Tommaso et al., 2012).

This was the scenario when, in 1998, the Department of Science and Technology of the Guangdong government decided to launch the 'one city, one product' program to support STs. It officially acknowledges as STs those 'townships' (or, less frequently, 'counties' or 'urban districts') with a yearly industrial output beyond RMB 2 billion (approx. US$316 million, at the September 2012 exchange rate), with at least 30% of their industrial output (or employment) concentrated in one industry that is called the 'specialized sector.'

The officially recognized STs are then eligible to receive a subsidy from the provincial government, with additional cofinancing from the local government. These funds have to be mainly used to establish an innovation platform or center, driving firms to upgrade their production capabilities and develop new technologies. The scope of the program is to not just target the single firm but also enhance the reputation of the whole town, possibly supporting the development of a common and easily recognizable brand (DSTGG, 2003).

Since the launch of the program, the number of acknowledged STs has been constantly increasing: there were 71 in 2003, 277 in 2008, and 326 in 2012. Also, their weight in the provincial economy has been growing: in 2001, they represented 3.66% of the total provincial GDP, while in 2010 they accounted for 28.5%. The growth is equally striking in terms of the number of enterprises (from 14 800 in 2001 to more than 950 000 in 2010) and industrial output of the specialized sector (from RMB 42 billion in 2001 to more than RMB 132 billion 9 years later) (Di Tommaso et al., 2012).

Analyzing the evolution of the acknowledged STs over time, it is possible to identify specific trends. In particular, in the first years, the aim was mainly to strengthen the central-eastern area of the province (the so-called Pearl River Delta area). In these last few years, however, in line with the new targets of the government, the recognition of STs seems to have tried to rebalance the territorial development of the province (with more towns acknowledged outside the Pearl River Delta) while at the same time incentivizing specific sectors (such as services or tourism).

In this way, the promotion of clusters in Guangdong has become an explicit industrial policy model: a tool used by the

government to address more general industrial development aims (Barbieri et al., 2012).

Final Remarks

SEZs in their different forms (industrial development parks, high-tech development zones, EPZs, and the like) and industrial clusters share some important features. They are, first of all, 'special territories' geographically based in specific areas of a country. Second, they are places where the agglomeration of different actors (firms as well as institutions, research centers, universities, and so on) takes place, which is often actively encouraged by governments. Finally, they are locations where such agglomeration can give rise to clustering advantages, and this is the main reason why such special territories can be seen and have been used as policy instruments for industrial development.

In the case of China (and of Guangdong Province, in particular), these tools have been extensively utilized and coordinated by local, provincial, and national governments. The Chinese experience of developing and managing STs and SEZs shows some specific features that can stimulate the debate on the use of such instruments for industrial development:

1. Specialization (in the same sectors or in closely related ones). The continuous intertwining between SEZs and agglomerations of specialized activities is a distinctive feature in China. For example, many of the first Chinese STs originated from industrial parks. Again, Shenzhen, the first and most famous Chinese SEZ, shows a strong specialization in the electronic sector, despite not hosting any formally acknowledged ST.
2. Geography of production. The choice of the location of SEZs and industrial parks and the dynamic of official recognition of STs suggest that the identification of 'special territories' is guided by strategic objectives where the spatial and geographical dimensions of industrial development play a central role.
3. Adaptive capacity to changing conditions. The experiences of both SEZs and clusters in China show that they have been interpreted as tools of a long-term industrial development strategy where the aims and targets are being adjusted according to the changing conditions. STs are today increasingly encouraged in remote areas in order to stimulate territorial rebalancing, SEZs acquire more and more the form of relocation parks, and the first SEZs now concentrate on the development of high-value-added goods and services.

The extent to which each one of these instruments has been effective in favoring growth and industrial development has to be verified. What is certain is that SEZs and STs have played a central role in the industrial development strategy of China country.

Abstract

Special education as a discipline is a broad field whose focus is the education of students with exceptionalities that includes support for career and college readiness. International practices in educating students with disabilities are emerging in many countries with varied levels of inclusive practice and educational benefit. Increasingly, there is a climate of school accountability, for example, in the United States with Common Core State Standards, and outcome assessments have placed pressure on schools and school districts to evaluate the quality of their teaching by way of student outcomes. The role of the special educator within the school is one that has various permutations from a primary interventionist who delivers instruction to a collaborator/co-teacher within an inclusive setting. This article will review the history of special education, current trends, and future considerations for the field.

The Discipline of Special Education

Special education is a field in education/educational psychology that is focused on the effective education for children with exceptionalities. Students with exceptionalities may have learning, behavioral, emotional, or social difficulties or may be gifted and talented. Twice exceptional students are those who are both gifted in an academic area and have a disability in another area (e.g., behavior, emotional control, or socialization). Special educators are trained broadly to address the needs of these students in a variety of public, private, and nonpublic settings. Provisions for credentialing as a qualified special educator vary but can include broad training that covers all exceptionalities or may subdivide credentialing into specific practice areas. Examples of these areas include mild to moderate and moderate to severe disability, educators of the deaf and hard of hearing, gifted and talented or emotional and behavioral disorders. Additional subdivisions may occur within age ranges (e.g., early childhood, elementary, and secondary aged students).

The Council for Exceptional Children (CEC; www.cec.sped.org) serves as the international professional organization representing the interests of students with exceptionalities by addressing the needs of government policy, standards for training, and professional development. CEC provides standards for knowledge, skills, and ethical principles and practice standards for the initial and advanced preparation of special educators as well as specialty standards for informing preparation programs. Accreditation by the Council for the Accreditation of Educator Programs (caepnet.org) of teacher licensure programs bases their accreditation decisions on CEC standards. The CEC's Division of International Special Education and Services provides support for the dissemination of practices internationally and communication in international forums and professional development.

International organizations advocate for educational practices that improve outcomes for individuals with disabilities as well as broader education agendas for countries to support economic and social progress in countries. The United Nations, United Nations Education, Science and Cultural Organization (UNESCO), and United Nations International Children's Emergency Fund (UNICEF), among others, have put forth positions and policies regarding the rights of children with disabilities to educational programs and monitor these practices across nations. The United Nations (2006) outlined their position on inclusive environments for individuals with disabilities in the Convention on the Rights of Persons with Disabilities. With regard to education, Article 24 outlines the need to reduce discriminatory practices with regard to education, the inherent value and potential of individuals with disabilities, and inclusion of individuals with disabilities in the general education environment with reasonable educational accommodations. Additionally, the convention outlined the need to educate individuals with disabilities on life and social skills needed to interact with the larger community. UNESCO, in partnership with UNICEF, monitors and supports the efforts for inclusive educational practices outlined in Article 24.

UNESCO provides information regarding policies and practices that are necessary to support individuals with disabilities in inclusive programs. Through their database, Inclusive Education in Action (IEA, 2011) provides examples from around the world on inclusive practices and training programs for teachers who serve as educators for these children. Policy guidelines are also provided for member states to utilize in developing their approaches to inclusive education. Consideration of barriers to inclusive education including attitudes toward individuals with disabilities, cultural influences, and teacher training needs are central components to developing an inclusive educational program, the emphasis being that educating students with exceptionalities is a benefit to society socially and economically.

Flexible learning environments, child-friendly environments, and a developmentally appropriate curriculum that includes content beyond academic skills are a common thread in current special education practices. Additionally, evidence-based practices, those practices that have support in the scientific literature, are increasingly important to provide these core areas of an inclusive environment. This requires additional training and professional development in both preservice and in-service training.

The Role of the Special Educator

Special educators are tasked with providing instruction that produces optimal outcomes for students with exceptionalities across academic, social, behavioral, and adaptive skills. In many countries, they are required, by law, to develop educational programs that are individualized for students with exceptionalities that lead to educational benefit that is objectively measurable. Special educators, in addition to providing or supporting instruction of students with exceptionalities, collaborate with other members of the educational team. The members of this team include the parents/caregivers of the student, related services personnel (e.g., speech and language pathologists, classroom teachers, and occupational therapists), administrators, and others as determined by the needs of the student and the wishes of the parent/caregiver. Instruction may occur in the general education classroom, a resource room where the student goes to receive primary or supplemental instruction or a significantly separate setting where a student may spend the majority of the day. Wherever instruction is delivered, evidence-based instructional strategies, informed by formative and summative assessments, serve as the foundation for the special educator to meet the educational needs of their students.

In other countries, with the emergence of educating students with exceptionalities, the role of the educator is more broadly defined and training may be less specialized than in those with more established programming. There are emerging educational programs housed in universities that train preservice teachers in teaching methodology and inclusive environments. The approach to education varies by region and cultural influences and differs from traditional western approaches of education. This requires the training for teachers across settings to differ. Similarities in outcomes, that is, independent community involvement, are evident.

Training in Special Education

Models of training that exist to train special educators broadly fall under two categories, university-based programs and alternative certification (AC) programs. Both exist to train preservice teachers. Within the United States, shortages in special educators over the past two decades (Boe, 2006) have led to the development of AC programs. Questions have been raised about the quality of these forms of training programs. Quigney (2010) summarized research on AC programs and reported that traditional programs generally produce better trained educators. She also outlined a format for discussing the benefits and concerns regarding AC programs since they were responding to the shortages noted in special education. Teachers prepared within AC programs reported challenges with classroom management and content knowledge (Casey et al., 2011). The evidence is not definitive as authors have reported higher rates of employment for teachers trained through the AC programs although their tenure of employment was shorter (Robertson and Singleton, 2010).

Internationally, particularly in those with emerging special education programs, the shortages are due to several factors, including overcoming attitudes toward students with exceptionalities within schools and the broader community and a lack of expertise in these emerging programs. International experts may be brought in to support these efforts and support program development both within schools and training programs through universities. Systems change, particularly at a national level in many cases, is challenging and requires the support of the national government, particularly ministries of education, to move these programs forward.

Learning Theories Applied

Educators' beliefs concerning how it is that students learn impact, in part, how they design and deliver instruction. These beliefs may reflect one or more learning theories, which are theories that help to explain how individuals come to acquire, access, and apply knowledge and skills. While numerous learning theories have been proposed over the past century, three core frameworks have emerged as paramount: behaviorist learning theory frameworks, cognitivist learning theory frameworks, and constructivist learning theory frameworks.

Behaviorist learning theory frameworks are concerned with observable indicators of learning and the conditioning of these observable behaviors. An educator who ascribes to a behaviorist learning theory framework would regard a student's ability to provide a target response when presented with a given stimulus (e.g., problem type) as evidence of learning. S/he would likely utilize instructional cues when teaching, provide reinforcement to help shape students' behavior (e.g., utilize a points or reward system in instructional contexts), provide students with ample opportunities to practice the target behavior, and structure learning tasks to ensure that students master basic skills before moving onto more complex, integrated learning tasks. Curricula reflecting a behaviorist learning theory framework utilize a scope and sequence of instruction and emphasize mastery learning for all students.

While behaviorist learning theory frameworks focus on observable behaviors as evidence of learning, cognitivist learning theory frameworks emphasize the role that cognition plays in learning and behavior. Fundamental to cognitivist learning theory frameworks is the belief that learning processes (e.g., memory, attention, perception) impact observable behaviors and these processes can be improved and/or supported in order to maximize student learning and performance. An educator who ascribes to a cognitivist learning theory framework would support students in developing background knowledge and schemata and would make the relationships among information overt. In the classroom, s/he would likely utilize graphic organizers, think-alouds, and performance assessments to scaffold and assess the learning process. Curricula reflecting a cognitivist learning theory framework feature well-organized and clearly structured content, concern for how perceptual features of materials are organized and presented, and a tandem emphasis on strategy instruction and acquisition.

Constructivist learning theory emphasizes the role that the learner, including his/her prior experiences and frameworks, plays in constructing new knowledge. An educator who ascribes to a constructivist learning theory framework would regard knowledge as created rather than acquired, and would

assume the role of guide and facilitator in the classroom. S/he would likely utilize collaborative, problem-based learning opportunities rather than predetermined instructional sequences, and would emphasize reflective practice. Curricula reflecting a traditional constructivist learning theory framework would emphasize 'discovery learning' driven by students' intrinsic motivation to explore and experiment, with minimal teacher guidance.

In the field of special education, research primarily reflecting behaviorist and cognitivist learning theories has informed the development of specialized academic and behavioral intervention curricula, and the individualization of educational programs for students with disabilities. Terms and phrases such as 'direct,' 'explicit,' 'systematic,' 'multisensory,' 'strategy-based,' and 'data-driven' often signal that a curriculum is grounded in such theory. Constructivist learning theories may be reflected in more advanced, applied learning contexts, but even so, are most often coupled with instructional approaches that are informed by behaviorist and cognitivist underpinnings.

Evidence-Based Practice

The term 'evidence-based practice' has been used in the field of medicine to refer to treatment practices that consistently yielded positive outcomes when delivered under experimentally controlled conditions (Odom et al., 2005). Three decades later, the No Child Left Behind Act (NCLB) of 2001 institutionalized the concept of utilizing scientific research (e.g., experimental, quasiexperimental, single-subject design; replicable findings; published in peer-reviewed venues) to inform educational practice. NCLB's definition of scientifically based research is likewise reflected in the 2004 reauthorization of the Individuals with Disabilities Education Act (IDEA), thereby affirming that scientific evidence should inform educational practice decisions in both general and special education contexts.

Defining 'evidence-based practice' for special education populations and settings has proven to be particularly challenging because of the complexity of the discipline, including the heterogeneity of disability presentations. This has often precluded researchers implementing true experimental inquiries (e.g., the random assignment of subjects to controlled and experimental conditions). Fortunately, Gersten et al. (2005) proposed a set of quality indicators for group experimental and quasiexperimental research in special education, and provided guidelines for how consumers could utilize these indicators to determine if a practice is evidence based. These quality indicators and guidelines continue to inform best practice in the field, and are referenced extensively in a CEC Division for Research White Paper titled *Thinking and Communicating Clearly About Evidence-based Practices in Special Education* (Cook and Cook, 2011).

Practitioners charged with selecting methods and materials for use with special student populations are also encouraged to consult the What Works Clearinghouse (WWC), a division of the United States Department of Education's Institute for Educational Sciences (IES). The WWC assesses the quality and findings of existing educational research and publishes their findings in the form of intervention reports. Here, it is possible to search for interventions by subject (e.g., reading, mathematics, and writing) and by name. While interventions included here may indeed have the backing of published research, it may be the case that the studies do not meet the evidence standards articulated by the WWC and, as such, no conclusion could be drawn about the efficacy of the intervention from an evidence-based standpoint.

This distinction highlights the difference between 'evidence-based practice' and 'research-based practice': 'research-based' programs often do not have the backing of published research that reflects the rigorous standards associated with the definition of scientific research proposed by NCLB, IDEA, and IES. This is the case, for example, when evaluating the efficacy of the Wilson Reading System® for students with learning disabilities. Of the 28 studies of the Wilson Reading System® employed with students with learning disabilities published between 1989 and 2009, none met the review protocol and evidence standards of the WWC. As such, given the standards of the IES, it could be argued that the Wilson Reading System® is best described as a 'research-based' versus 'evidence-based' intervention for students with learning disabilities.

CEC's Division for Research makes clear, however, that methods and materials that do not presently meet rigorous evidence-based practice standards for a given population of students should not summarily be disregarded. Rather, special educators are advised to utilize professional judgment when selecting interventions and to employ informed progress monitoring practices (see below) to monitor the efficacy of interventions provided.

Special Education Frameworks

All learners can benefit from different aspects of special education services, but most do not reach the level of legally requiring such services for success in school. The current principles of special education rely on the concept that delivering many of these services through the general education environment will help support more learners, regardless of their level of need. These principles are oftentimes delivered through the frameworks of Positive Behavioral Interventions and Supports (PBIS) and Response to Intervention (RtI). The goal of these frameworks is to allow all students the optimal opportunity to learn in the general education environment by using special education strategies to support the learning of all students. When more intensive strategies are required, these frameworks allow use of more directed interventions to assess whether a child with inimitable needs is responsive to such interventions. These systems are designed to elevate the number of students receiving effective interventions in the general education environment while lowering the number of students being referred to special education and thus removed from the general education environment.

Both PBIS and RtI are tiered frameworks that are designed to use differentiated instruction as soon as a problem is noted. PBIS uses this approach to address behavioral concerns while RtI is principally engaged in academic remediation. Both

systems are intended to address problems in a timely and effective manner by using quick response time and effective practices.

While PBIS was initially established as a framework in the United States, it is being implemented in over 15 countries worldwide. Several countries have national initiatives supporting the implementation. Countries implementing PBIS (or SW-PBS) include New Zealand, Australia, Canada, Netherlands, Sweden, Norway, Finland, Denmark, Portugal, Turkey, Spain, Italy, France, Germany, and Hungary (T.J. Lewis, personal communication, 5 February 2014; G. Sugai, personal communication, 4 February 2014).

Positive Behavioral Interventions and Supports

PBIS (also referred to as School-wide Positive Behavior Supports) is considered a framework upon which each individual school can scaffold its expectations for community behavior and respect. It is a primary prevention system designed for all students with additional supports provided for some students. Since PBIS is a framework and not a predetermined curriculum, the expected behaviors are developed from within the school community and are unique. PBIS is currently implemented in over 18 000 schools (www.pbis.org).

PBIS consists of three tiers of intensity. The first tier is implemented school-wide and consists of rules and expectations of behavior, typically both physical and social behavior. Rules and expectations are explicitly taught to all community members, with positive reinforcement systems ingrained in the program along with a continuum of consequences for problem behaviors. Inherent to this framework is the expectation that data be kept on multiple variables and assessed periodically for effectiveness.

Those students who do not respond well to the first tier of PBIS, based on data, begin to receive services through a second tier. This tier typically consists of about 10–15% of the school population. This tier is not implemented school-wide but is focused on smaller groups of students with similar behavioral concerns. These students are considered at-risk for serious behavior problems and the purpose is to prevent such development. Interventions in the second tier are often focused on student needs relating to peer relationships, low academic achievement, and challenging home environments (Ennis et al., 2011). These interventions are research based with data kept on their effectiveness.

The third tier is comprised of students with serious or chronic problem behaviors, which is typically about 5% of the school population. Students in tier 3 receive intensive, individualized research-based interventions to remediate their problem behaviors. Again, data are kept and analyzed to determine the effectiveness of each intervention implemented. Students who do not show positive response to tier 3 interventions are then referred for special education consideration.

Based on a literature review searching for evidence-based effective research practices, Simonsen et al. (2008) summarized the best classroom management practices as the following: "(a) maximize structure; (b) post-teach, review, monitor, and reinforce expectations; (c) actively engage students in observable ways; (d) use a continuum of strategies for responding to appropriate behaviors; and (e) use a continuum of strategies to respond to inappropriate behaviors" (Simonsen et al., 2008: 353). Within those overarching themes are effective tier 1, 2, and 3 practices such as physical classroom layout recommendations, rates of opportunities to respond, response cards, direct instruction techniques, guided notes, group contingencies, specific and contingent praise, etc. An outstanding source for educators on effective interventions is found at the WWC website (http://ies.ed.gov/ncee/wwc/).

Response to Intervention

RtI is a tiered framework that mirrors PBIS but through addressing academic problems in addition to behavior problems. RtI is a legal requirement in the United States under the latest iteration of IDEA and is thus expected to be implemented throughout that country's public schools. However, it is a visual and theoretical representation of the best practices of special education teaching that have existed worldwide for years (http://www.ldworldwide.org/pdf/rti/rti-series-1-what-is-rti.pdf). It is comprised of high-quality, differentiated instruction that is matched to a student's needs. The progress, or lack thereof, that the student makes is recorded and monitored frequently to assess effectiveness. Implementation of RtI is considered by some special education directors to be less complicated at the elementary level than at the secondary level (Sansosti et al., 2011), but is nonetheless an effective means of early intervention for students with academic needs.

An example of math interventions that can be implemented through the RtI tiered framework is given here to exemplify the system. A moderately effective tier 1 intervention includes screening students in the classroom who are at risk for math difficulties and providing interventions (Gersten et al., 2009). Some tier 2 and tier 3 interventions include using explicit and systematic instruction (providing models of useful problem solving, verbalizing effective thinking, guided practice, corrective feedback, and frequent review), use of visual representations of math concepts, and 10 min at every grade level devoted to review of basic math facts (Gersten et al., 2009). Through this tiered framework, at-risk students are identified early and appropriate interventions are administered and monitored to remediate difficulties prior to escalation of learning problems.

Universal Design for Learning

PBIS and RtI address behavior and academic problems through differentiated instruction and intervention. Another model of instruction that is currently in the field of special education similarly concentrates on success in the general education environment but does so through Universal Design for Instruction (UDI). Through this model, instruction and assessment in the classroom are designed specifically to allow optimum access to the materials for a wide variety of students, including those with physical and cognitive challenges (http://www.udlcenter.org). It is another means of supporting access to the general education curriculum for all students, through a flexible, positive framework of instruction.

UDI is an adaptation of the Universal Design concept from architecture. The concept is that the design of a building entrance, for example, be made usable by people with a variety of characteristics and needs. A traditional door at a building entrance is accessible to those with the ability to turn a knob, pull the door, step back from the door to allow it to swing, and hold it open to their side while they walk through. However, a door that senses someone's presence and automatically opens is also accessible to someone carrying a heavy box, pushing a stroller, ambulating in a wheelchair, and ambulating on crutches, as well as a small child (Burgstahler, 2009). This design is thus more universally usable, not just for those with disabilities. With UDI, instruction is made universally accessible in the same manner. In instruction, these are addressed through class climate (ensure a welcome and open environment where students can express their unique learning needs), interaction (offer interaction opportunities that are accessible to all, such as having a microphone to broadcast the speaker's voice), physical environments and products (develop a plan for safe egress for all students in an emergency), delivery methods (use multiple formats to deliver content), information resources and technology (post assignments early so students can begin projects early in the secondary school grades), feedback (provide prompt and useful feedback), assessment (use a variety of assessment types, such as short answer and multiple choice tests, papers, group and individual projects, etc.), and accommodation (be prepared to allow extra time to all test takers, if necessary, and be prepared for special accommodations for areas not met by UDI) (Burgstahler, 2009).

There are numerous research-based interventions that are effectively utilized through PBIS, RtI, and UDI. The keys to current best-practice international special education instruction are that it is based on proven interventions, data are kept and monitored to evaluate intervention effectiveness, and delivery of interventions begins immediately after problems are identified. Flexible and proactive delivery of instruction and expectations are also utilized to create environments of success for all students.

Future Directions and Issues in Special Education

Given the focus of special education and the needs for evidence-based practices for inclusion, instructional strategies and pedagogical knowledge is needed. While frameworks derived from special education research are now providing systemic approaches to addressing the needs of all students, more work is needed in developing instructional methodology that can be applied to students with varying abilities and exceptionalities that will lead to improved outcomes for all students. Continued research on universally applicable instructional methods is needed in this regard. Alternative teaching arrangements such as co-teaching arrangements that employ both a general and special education teacher in the classroom and other models will be supportive of these efforts. Increased collaboration between general and special educators in classroom settings will support these efforts (Friend et al., 2010; Solis et al., 2012).

High-quality teacher preparation for both general and special educators is a continuing effort and one that is central to developing competent, inclusive programs. Standards to general educators to be better informed on the needs of students with exceptionalities in their classrooms will support these students' participation in inclusive settings. Core competencies in classroom management, differentiated instruction, assessment, and tiered interventions for general educators will become increasingly necessary in the coming years and allow for a responsive system of instruction that will support inclusive programming. For special education preparation, efforts to identify competencies necessary to support and provide primary instruction to students are being undertaken.

Disproportional representation in special education is a concern in many countries. In established programs in special education, overrepresentation of nonnative speaking learners, students of immigrant status, and low-income students continues to be an issue in education (Algozzine, 2005) that requires redress with regard to eligibility, instruction, and educational outcomes. Efforts to involve community, families, and the school in complementary and collaborative efforts to improve outcomes including supplemental learning opportunities, family involvement, building in community supports, and outreach efforts are being evaluated for their effectiveness in bridging the achievement gap. It will be critical as inclusive school programs continue to develop internationally that these students are appropriately supported.

This article is a revision of the previous edition article by J.D. Smith, volume 22, pp. 14847–14851, © 2001, Elsevier Ltd.

Abstract

The development of special education in the United States has largely been led by developments that have occurred through federal legislation and litigation. The purpose of this article is to trace and briefly describe the legal history of special education. I trace the eight critical legal developments that have affected, and continue to greatly influence, the education of students with disabilities in public schools. I conclude by highlighting the many improvements in the lives of students with disabilities engendered by special education law.

The rights of children and youth with disabilities in the United States to receive special education services were gained largely through the tireless efforts of parents and advocacy groups in the courts and legislatures of this country. This legal history of special education can be characterized as movement from the exclusion of students with disabilities in public education to inclusion. In this article, I will trace the eight most critical historical events that have influenced the development of special education in the United States.

Critical Event #1: The Enactment of Compulsory Education Laws in the United States

Massachusetts was the first state to pass a compulsory education law in 1852 and Vermont passed the second in 1867. By 1918, compulsory education laws were in place in all states. Unfortunately, despite the enactment of these compulsory education laws, children with disabilities were often excluded from public schools. For example, in 1934, the Cuyahoga County Court of Appeals in Ohio ruled that the state statute mandating compulsory attendance for children ages 6 through 18 years gave the State Department of Education the authority to exclude certain students. The Ohio statute was an example of laws that mandated compulsory education, supposedly for all students, while simultaneously allowing school districts and states to exclude students with disabilities from public schools. It was widely believed that students with disabilities would not benefit from an education or that their presence may be disruptive to other students. In fact, as late as 1958, the Illinois Supreme Court ruled that compulsory attendance laws did not apply to children with 'mental impairments' and in 1969, it was a crime in North Carolina for parents to attempt to enroll their child with disabilities in public schools after the child had been excluded.

Critical Event #2: Parents Advocating for Their Children with Disabilities and the Formation of National Advocacy Groups

Because their children with disabilities were often excluded from public school, parents became advocates for ensuring the educational rights of their children. This advocacy paved the way for a national reexamination of the exclusion of students with disabilities from public schools. One of the first events addressing the exclusion of students with disabilities from public schools was the White House conference of 1910. A primary goal of this conference was to define and establish remedial programs for children with disabilities and special needs. This conference led to an increased interest in educating children with disabilities in public school settings rather than institutionalizing them.

In the years following the White House conference, the numbers of segregated classes and support services for students with disabilities in public schools increased significantly. Unfortunately, despite the increase in special education classrooms, many children and youth with disabilities were not identified for services or struggled in classrooms that were not appropriate for their needs. Moreover, in the 1930s, there was a decline in support for special education for students with disabilities and a decrease in the number of special education programs. This may have been due to the economic difficulties of these times. Additionally, the special education programs that did exist in public schools tended to be more restrictive and of a custodial, rather than educational, nature.

In response to the decreasing quality and numbers of special education programs in public schools, parents and educators began to come together to form groups that advocated for the educational rights of students with disabilities. For example, in 1933, the first such group formed in Cuyahoga County, Ohio. The Cuyahoga County Ohio Council for the Retarded Child consisted initially of five mothers of children with mental retardation who banded together to protest the exclusion of their children from school. The efforts of these parents resulted in the establishment of a special class for their children, sponsored by the parents themselves. Similar types of local groups were established throughout the nation during the 1930s and 1940s. In the 1950s, such groups came together to form advocacy groups on the national level. The National Association for Retarded Citizens (now the Association for Retarded Citizens) was organized in Minneapolis, Minnesota, in September 1950. Forty-two parents and concerned individuals from 13 local and state organizations met to establish what has become a powerful and significant organization of parents, families, and other persons with an interest in

improving services for persons with mental retardation. Other groups of parents and educators that became nationally prominent professional organizations include the Council for Exceptional Children, the Association for Persons with Severe Handicaps, the Autism Society of America, the United Cerebral Palsy Association, the National Association for Down Syndrome, and the Association of Children with Learning Disabilities. The advocacy movement was critical to the development of special education services. The activities of interest groups also provided information, stimulus, and support to the Congress when considering, developing, and acting on legislation. The formation of these national advocacy groups, therefore, was very important to the development of special education in the United States.

Critical Event #3: The US Supreme Court's Ruling in *Brown v. Board of Education*

In the 1950s and 1960s, the civil rights movement sought changes in society that would allow minorities, particularly African-Americans, equality of opportunity. These efforts led to litigation and changes in legislation in education. This legislation provided greater constitutional protection for minorities, and eventually for persons with disabilities. A landmark case, *Brown v. Board of Education* (1954), was a major victory for the civil rights movement and became an underpinning for further civil rights action. The *Brown* decision not only had a tremendous impact on societal rights for minorities, but also affected many aspects of educational law and procedure. Although it took time, the precedents set in *Brown* resulted in sweeping changes in schools' policies and approaches to students with disabilities.

State-mandated segregation of the races in the schools denied black students admission to schools attended by white students. The plaintiffs maintained that the practice of segregating schools was inherently damaging to the educational opportunities of minorities, that segregated public schools were not – and could not be made – equal, and that segregated public schools violated black students' constitutional rights under the 14th Amendment. As an extension of this argument, the Court maintained that state-required or state-sanctioned segregation solely on the basis of a person's unalterable characteristics (e.g., race) was unconstitutional. The high court also determined that segregation solely on the basis of race violated equal protection and denied children from minority backgrounds equal educational opportunity. This decision opened up a number of legal avenues for those seeking redress for students with disabilities. In *Brown*, the high court reasoned that because of the importance of education in our society, the stigmatizing effects of racial segregation, and the negative consequences of racial segregation on the education of those against whom segregation was practiced, segregated public schools denied students equal educational opportunities.

The ruling in *Brown v. Board of Education* has had a major influence on education law in the United States. The influence of this seminal decision was less direct in special education law, whereas it was, nonetheless, important in the history of special education. This is because advocates for improving educational opportunities for children and youth with disabilities saw the basic truths of *Brown v. Board* as equally applicable to the children for whom they advocated.

Critical Event #4: Federal District Court Rulings in the Educational Opportunity Cases

Sixteen years after the *Brown* decision, two seminal federal district court cases applied the concept of equal opportunity to children with disabilities. The two landmark decisions in which action was brought against state statutes and policies that excluded students with disabilities were *Pennsylvania Association for Retarded Citizens v. Pennsylvania* (1972) and *Mills v. Board of Education of the District of Columbia* (1972).

In January 1971, the Pennsylvania Association for Retarded Children (hereafter referred to as *PARC*) brought a class action suit against the Commonwealth of Pennsylvania in federal district court. The plaintiffs argued that students with mental retardation were not receiving publicly supported education because the state was delaying or ignoring its constitutional obligations to provide a publicly supported education for these students, thus violating the students' rights under both state statute and the Equal Protection clause of the 14th Amendment to the US Constitution. Witnesses for the plaintiffs established four critical points. The first was that all children with mental retardation are capable of benefiting from a program of education and training. Second, education cannot be defined as only the provision of academic experiences for children; it also includes experiences such as learning to clothe and feed oneself. A third point was that, having undertaken to provide all children in the Commonwealth of Pennsylvania with a free public education, the state could not deny students with mental retardation access to free public education and training. A final stipulation was that the earlier students with mental retardation were provided education, the greater the amount of learning that could be predicted, a point related to denying preschoolers with retardation access to preschool programs available to children without disabilities. *PARC* was resolved by consent agreement specifying that all children with mental retardation between the ages of 6 and 21 years must be provided a free public education, and that it was most desirable to educate children with mental retardation in a program most like the programs provided for their peers without disabilities. The decree, which was amended a year later, set the stage for continued developments regarding the educational rights of students with disabilities.

Soon after the *PARC* decision, a class action suit was filed in the federal district court for the District of Columbia. This suit, *Mills v. Board of Education* (1972; hereafter *Mills*), was filed against the District of Columbia's Board of Education on behalf of all out-of-school students with disabilities. The action was brought by the parents and guardians of seven children who presented a variety of disabilities, including behavior problems, hyperactivity, epilepsy, mental retardation, and physical impairments. These seven children were certified as a class, thereby representing more than 18 000 students who were denied or excluded from public education in Washington, D.C. The suit, which was based on the 14th Amendment, charged that the students were improperly excluded from school without due process of law. The court held that because

segregation in public education on the basis of race was unconstitutional, the total exclusion of students with disabilities was also unconstitutional. *Mills* resulted in a judgment against the defendant school board mandating that the board provide all children with disabilities a publicly supported education. In addition, the court ordered the district to provide due process safeguards.

The *PARC* and *Mills* decisions set precedent for similar cases to be filed across the country. In the 2 1/2 years following the *PARC* and *Mills* decisions, 46 right-to-education cases were filed on behalf of children with disabilities in 28 states. By the early 1970s most states had passed laws that required public schools to provide education to students with disabilities. The laws in the various states were quite varied, however, with some states having strong laws, some states having weak laws, and some states having no laws ensuring the educational rights of students with disabilities. Because of the unevenness of these laws, a federal standard was needed.

Critical Event #5: Early Involvement by the Federal Government in Education

The first significant federal involvement in the education of students with disabilities occurred in the late 1950s and early 1960s. Some of these early efforts included the Education of Mentally Retarded Children Act of 1958, in which Congress appropriated funds to train teachers of children with mental retardation, and the Training of Professional Personnel Act of 1959, which helped train leaders to educate children with mental retardation. In 1965, the Elementary and Secondary Education Act (ESEA) was passed and signed by President Lyndon Johnson as an important component of the war on poverty. The ESEA provided federal money to states to improve educational opportunities for disadvantaged children, including students with disabilities who attended state schools for the deaf, blind, and retarded. This law was the first time the federal government provided direct funding to the states to assist in educating certain groups of students. This law was a precursor to the laws that would provide direct assistance to states for educating students with disabilities.

In 1970, the Education of the Handicapped Act (EHA) became law. The EHA, which was to become the framework for legislation that followed, consolidated and expanded previous federal grant programs for educating students with disabilities and continued funding pilot projects at the state and local levels. The law also provided funding to institutions of higher education to develop programs to train teachers of students with disabilities and authorized funding for the development of regional resource centers to provide technical assistance to state and local school districts. The Education Amendments of 1974 authorized the creation of the National Advisory Council on Handicapped Children. The purpose of the amendments was to require that states receiving federal funding established goals for providing full educational opportunities for all students with disabilities. The law also provided funding for programs and specified due process procedures. The passage of these laws created many of the rights that would be included in later laws granting educational rights to students with disabilities. The early laws, however, had few enforcement mechanisms.

In 1973, Congress passed the Rehabilitation Act of 1973. Section 504, a short provision of this act, was the first federal civil rights law to protect the rights of persons with disabilities. According to the law, no handicapped person in the United States could, solely by reason of his or her handicap, be excluded from participation in, be denied the benefits of, or be discriminated against under any activity receiving federal financial assistance. The language of the law was very similar to the language in other federal civil rights laws (such as Title VII of the Civil Rights Act, which prohibited discrimination on the basis of race, and Title IX of the Education Amendments of 1972, which prohibited discrimination based on sex). Thus, the primary purpose of Section 504 was to prohibit discrimination against a person with a disability by any agency receiving federal funds, such as schools and universities. This includes students with disabilities attending preschool, elementary, secondary, or postsecondary education. Section 504 also required agencies covered by the law to provide assurances of compliance, to take corrective steps when violations are found, and to make individualized modifications and accommodations to provide services that are comparable to those offered to persons without disabilities.

Section 504 included a very broad definition of disability. The law protects from discrimination any person who has a physical or mental impairment that substantially limits one or more of the person's major life activities (e.g., learning, breathing, walking). Because of the expansive definitions of disability, Section 504 protects all students with disabilities, whether they receive special education services or not.

Critical Event #6: The Passage of the Education for All Handicapped Children Act

In 1975, President Ford signed the Education for All Handicapped Children Act (EAHCA) into law. The EAHCA, which was often referred to as P.L. 94-142 (the EAHCA was the 142nd Public Law passed by the 94th Congress), combined an educational bill of rights for students with disabilities with the promise of federal financial incentives to participating states. To receive funding, states had to develop policies ensuring that all qualified students with disabilities would receive a special education program meeting the requirements of the EAHCA. Funding would flow from the federal government to the state educational agencies and, finally, to local educational agencies (LEAs). To receive the funds, states had to submit plans that meet the federal requirements. Local school districts, in turn, had to have programs meeting the state requirements. The federal funding that states received would be based on an annual count of all children and youth served under the law. Thus, the EAHCA made the federal government a partner with the states in educating students with disabilities who were covered by the law.

In the EAHCA, the following categories of disability were eligible for special education services (some of these categories were added in later amendments to the EAHCA): autism, deaf-blindness, deafness, emotional disturbance, hearing impairment, intellectual disability (formerly known as mental retardation), multiple disabilities, orthopedic impairment, other health impairment, specific learning disability, speech or

language impairment, traumatic brain injury, and visual impairment (including blindness).

The purpose of the EAHCA was to ensure that all eligible students with disabilities were provided with a free appropriate public education (FAPE) that emphasized special education and related services designed to meet their unique needs and prepare them for further education, employment, and independent living. Thus, the focus of the EAHCA was to ensure that children and youth with disabilities have access to public education, and that this education be developed to meet their individual needs. To ensure that an eligible student's program of special education meets his or her unique needs, teams of persons from the student's school, which included the student's parents, would meet at least annually to collaboratively develop an individualized education program (IEP). A student's IEP is the blueprint of his or her special education program that must, according to the EAHCA, ensure that the student receives FAPE. Table 1 depicts the major principles of the EAHCA.

The EAHCA also included a system of procedural safeguards, which are legal checks and balances that protect the educational rights of children with disabilities and their parents. The procedural safeguards give a student's parents the right to contest in a due process hearing any aspect of their child's identification, evaluation, or program and even to file a suit in state or federal court to receive services. In fact, special education was soon to become a highly litigated area.

Table 1 The major principles of the EAHCA

Principle	*Description*
● Zero reject	● Local education agencies (LEAs) are required to locate, identify, and provide services to all eligible students with disabilities.
● Protection in evaluation	● LEAs must conduct a full, fair, and individualized evaluation to determine if a student has an IDEA-related disability and if the student needs special education services.
● Free appropriate public education	● LEAs are required to deliver an individualized program of special education services that confer meaningful educational benefit to a student.
● Individualized education program	● The vehicle by which school personnel and a student's parents develop a student's special education program. It is both a process for determining the program and a document outlining it.
● Least restrictive environment	● Students with disabilities must be educated to the maximum extent appropriate with students who are not disabled.
● Procedural safeguards	● A system of checks and balances to ensure that students with disabilities are afforded their rights under the EAHCA.
● Parental participation	● LEA personnel must collaborate with a student's parents in developing their child's special education program.

One of the important developments in the EAHCA was contained in a section of the law, now known as Part D, that required federal funds be invested in improving education for students with disabilities. Part D is intended to reform and advance personnel preparation and professional development in early intervention, special education, and transition services in order to improve results for children with disabilities. Through this section, the US Department of Education has invested millions of dollars in research, training, and technical assistance centers that actively support and advance effective practices for educational programming for students with disabilities. The law also funds parent training and information centers and community parent resource centers that support programs to educate and assist parents. Moreover, the law supports educators through grants to fund the preparation of special education teachers and their continuing education through professional development in research-based programming. The accomplishments of these investments are monumental and have led not only to improvements in special education, but also to meaningful improvements in the lives of all persons with disabilities.

In 1977, the US Department of Education issued the final regulations implementing the EAHCA. These regulations, which took effect at the start of the 1977–1978 school year, provided guidance for states and school districts developing special education programs in conformity with the EAHCA.

Critical Event #7: The US Supreme Court's Ruling in *Board of Education v. Rowley* (1982)

The US Supreme Court has heard a number of special education cases. Of these cases, arguably the most important was the first special education case heard by the court: *Board of Education of the Hendrick Hudson School District v. Rowley* (1982). In this case, the Court addressed the requirement in the EAHCA that students in special education receive FAPE.

Amy Rowley, a student at the Furnace Woods School in the Hendrick Hudson Central School District, was deaf and entitled to FAPE under the EAHCA. The year before Amy was to attend first grade at Furnace Woods, a meeting was held between her parents and school officials to determine future placement and special education services. The IEP team decided to place Amy in the regular kindergarten class to determine what supplemental services she might need. In addition to the special education services that were proposed, Amy's parents requested that a sign language interpreter be provided as part of her special education program. A sign language interpreter was placed in Amy's classroom for a trial period. But when Amy's IEP was developed for first grade the following year, a sign language interpreter was not provided.

Amy's parents then requested a due process hearing. In the ruling, the hearing officer agreed with the school district that federal law did not require the interpreter. The Rowleys appealed the decision to the New York Commissioner of Education. The Commissioner upheld the hearing officer's decision. Amy's parents then sued in federal district court, claiming that the district's refusal to provide a sign language interpreter had denied Amy FAPE.

Although Amy was doing better than the average child, the court ruled that Amy was not learning as much as she could without her handicap. Because of the disparity between Amy's actual achievement and her potential achievement, the district court ruled that Amy had been denied FAPE. The school district then appealed the decision to the US Court of Appeals for the Second Circuit. The appellate court affirmed the lower court's ruling. The school district then appealed the decision to the US Supreme Court. The high court granted certiorari (i.e., decided to hear the case). The high court considered two questions: (1) What is FAPE and (2) what is the role of state and federal courts in reviewing special education decisions?

In the majority opinion, Supreme Court Chief Justice Rehnquist wrote that FAPE consisted of educational instruction designed to meet the unique needs of a student with disabilities, supported by such services as needed to permit the student to benefit from instruction. The Court noted that the EAHCA required that these educational services be provided at public expense, meet state standards, and comport with the student's IEP. If the special education program allowed a child to benefit from educational services and was provided in conformity with the IEP and other requirements of the EAHCA, the student was receiving FAPE. Justice Rehnquist also wrote that any substantive standard prescribing the level of education to be accorded students with disabilities was conspicuously missing from the language of the EAHCA. Thus, the Court held that the EAHCA did not require the Hendrick Hudson school district to provide a sign language interpreter for Amy Rowley.

Critical Event #8: The Amendments to the EAHCA

The EAHCA has been reauthorized and amended a number of times since its original passage in 1975. Important amendments to the law were passed in 1986, 1990, 1997, and 2004.

The first amendments to the EAHCA, titled the Handicapped Children's Protection Act of 1986, authorized the award of reasonable attorney's fees to prevailing parties in special education lawsuits. The same year the EHA amendments required participating states to provide early intervention services to children with developmental disabilities from birth to their third birthday. Moreover, children from age 3 to 5 years were included under the federal law, thereby requiring schools to serve children with disabilities in special education programs.

In the 1990 amendments to the EAHCA, the name of the law was changed to the Individuals with Disabilities Education Act (IDEA). The law also (1) removed the term 'handicapped' and substituted the term 'disability'; (2) incorporated 'person-first' language, which puts the focus on the student rather than the label or category of disability (so instead of referring to a 'handicapped child,' the law used the phrase 'child with disabilities'); (3) added the categories of autism and traumatic brain injury to the list of eligible disabilities under the law; and (4) included a requirement to provide transition services for students by age 16 years.

The IDEA amendments of 1997 further strengthened the educational rights of students with disabilities. In fact, according to the House report on IDEA 1997, a major goal of IDEA 1997 was to improve and increase the educational achievement of students with disabilities. The IDEA amendments required that (1) students with disabilities would have access to the general curriculum and that the general educator would play a larger role in the process of developing a student's IEP, (2) IEP teams were to consider factors such as assistive technology and student behavior problems when crafting a student's IEP, (3) a student's parents were explicitly made a part of the team that makes eligibility and placement decisions for their child with disabilities, and (4) mediation should be used in resolving disputes between school personnel and a student's parents. The IDEA amendments of 1997 also addressed the issue of discipline, as Congress attempted to balance the need for discipline in schools with the requirement that special education students receive FAPE. To accomplish this, the law required that IEP teams consider positive behavior supports and interventions to address a student's problem behaviors in an effort to remediate and educate rather than merely punish.

In 2004, the Individuals with Disabilities Education Improvement Act (IDEIA) reauthorized and amended the IDEA. An important Congressional goal in passing IDEIA was to align IDEA with the ESEA, formerly referred to as No Child Left Behind, thereby increasing accountability for improving student performance. Thus, IDEIA included measures to increase academic results for students with disabilities such as requiring the use of scientifically based practices. The law also defined highly qualified special education teachers in line with the definition in the ESEA. Additionally, Congress sought to reduce the paperwork burden on teachers, expand options for parents, and reduce litigation.

The IDEIA also allowed school districts to spend up to 15% of their IDEA Part B funds on early intervening services (EIS) for students in kindergarten through grade 12, with an emphasis on students in kindergarten through grade 3, who had not been identified as needing special education or related services but who need additional academic and behavioral support to succeed in the general education environment. The purpose of this provision was to enable LEAs to identify young students who were at risk for developing academic and behavioral problems while they were still in general education settings, and then to address these problems by delivering interventions in a systematic manner by using research-based academic and behavioral interventions along with progress-monitoring systems. To implement EIS services, school district personnel would (1) provide school-wide academic and behavioral assessments for all students; (2) implement school-wide academic and behavioral services to students identified as needing additional services, including scientifically based reading instruction and positive behavior support systems; and (3) offer professional development activities to teachers and other school staff to enable them to deliver scientifically based academic and behavioral interventions.

Accomplishments Produced by Special Education Laws in the United States

In the early 1970s, efforts to ensure that students with disabilities received a public education that was appropriate to their individual needs began on the federal level. Before the 1970s, more than a million children with disabilities received no education whatsoever and many others received an

education that was not suited to their needs, often receiving such services in segregated settings. Additionally, many children with developmental disabilities were housed in institutions that focused on children's basic care needs rather than education. In 2014, almost 45 years after the original court cases, the battle to ensure access to public education for students with disabilities has been won. Today, access to public education is ensured for the approximately 12% of all public school students who have disabilities, over 6.5 million children, no matter how severe their disabilities may be. Moreover, programming now begins as soon a child is identified as having a developmental delay, even in infancy, which has led to many young children with disabilities and their families receiving high-quality early interventions that prevent or reduce the need for future services. Children with disabilities have gone from either being totally excluded from education or learning in segregated settings to learning in classrooms alongside their nondisabled peers in their neighborhood schools. More youth with disabilities now graduate from high school and over 30% enroll in postsecondary education. Additionally, trends in postschool employment of youth with disabilities have shown positive increases.

Clearly, special education laws in the United States have led to improvements in the lives of children and youth with disabilities. Much of the credit for this progress is due to parents of children and youth with disabilities who fought long and hard for their children's educational rights. These actions led to court cases and legislation at both the state and national levels, such as Section 504 of the Rehabilitation Act and the IDEA, which have been a major impetus for change. The protections of these laws have led states and school districts to focus on the education of students with disabilities and have led to a system of special education in the United States in which children and youth with disabilities are identified, their unique educational needs are assessed, meaningful programming is developed, and their progress in education is monitored and evaluated. Moreover, the research supported by the IDEA has increased the abilities of teachers to successfully work with students using evidence-based strategies and procedures. Special education laws in the United States have led to the creation of a system that has spread to many nations in the world.

Despite these impressive gains, the system can still be improved. For example, many students with disabilities still drop out of school, have difficulty finding jobs, and lead lives of dependency. To meet these challenges, special education laws will need to remain focused on ensuring the quality of educational experiences, fund research to improve programming, and stress accountability for results. These efforts, which began with the 1997 and 2004 amendments to the IDEA, will continue to ensure that students with disabilities receive a meaningful education, which in turn, will lead to an improved quality of life.

Abstract

The multiplication of scientific activities has brought a division of labor. The history of scientific advancement is a history of concatenated specialization. There is more communication between specialties belonging to different disciplines than between specialties within the same discipline. Specialization within disciplines, accompanied by their fragmentations, is the first process. Recombination of specialties across disciplinary borders is the second. Such a recombination has been called hybridization. A hybrid is a combination of two branches of knowledge. Many of the most creative specialties are hybrid specialties. Recombination of specialties appears in the borrowing of concepts, theories, and methods. The citation patterns in academic publications permit the analysis of the process of specialization and recombination by interferences of disciplines. A distinction is needed between interdisciplinary amalgamation and hybridization. Diminishing marginal returns have been perceived in the core of disciplines and a high productivity at their margins. This phenomenon has been called the paradox of density.

Specialization is an old phenomenon, observed as early as Auguste Comte. Recombination of specialties is also an old trend: Robert Merton noticed it in the early 1960s: "the interstices between specialties become gradually filled with new cross-disciplinary specialties" (Merton, 1963: p. 253). The multiplication of scientific activities and the growing complexity of knowledge have brought a division of labor, visible in increasing expertise in all domains. The history of scientific advancement is a history of concatenated specialization. In spite of this evidence, "even since the social sciences began to develop, scholars have repeatedly expressed apprehension about the increasing fragmentation of knowledge through specialization" (Smelser, 1967: p. 38).

Fragmentation and specialization are the two faces of the same coin. This double process is a condition of scientific advancement. The term 'discipline' is inherited from the vocabulary of the nineteenth century and is understood as a branch of instruction for the transmission of knowledge and as a convenient mapping of academic administration. In all universities, teaching, recruitment, promotion, peer review, and financing are still organized along disciplinary lines, but the great scientific laboratories and the most creative research centers are anchored on specialties, which in many cases cross the borders of formal disciplines, or are located at the interstices between disciplines. In the sociology of science the term 'discipline' is defined as a 'cluster of specialties' (Crane and Small, 1992: p. 198), the specialty being the main source of academic recognition and of professional legitimation (Zuckerman, 1988: p. 539).

In the natural sciences, specialization is celebrated as a mark of competence. Each contemporary natural science from astronomy to zoology is a conglomerate of dozens of specialties. Only in some social sciences, particularly in sociology, political science, psychology, and anthropology, does one hear complaints and lamentations about the fragmentation of the discipline into specialties. The word 'crisis' appears in the title of many books and articles about the identity and the contours of these disciplines (Horowitz, 1993; Turner and Turner, 1990). In reality, such 'crises' are symptoms of growth and expansion.

[†] Deceased.

Specialization

Analysis means breaking things into parts. All sciences have made progress, from the sixteenth century on, by internal differentiation and cross-stimulation among emergent specialties. Each specialty developed a patrimony of knowledge. With the growth of these patrimonies specialization became a necessity. Increasing specialization has led to the creation of subdisciplines. A specialty requires a high qualification in a delimited domain. The process of specialization has tended to disjoin activities which had previously been united, and to separate scholars belonging to the same formal discipline, but who are interested in different fields. Specialties are considered as parts of a larger discipline but "the modern scholar normally does not attempt to master his discipline in its entirety. Instead he limits his attention to one field, or perhaps two" (Somit and Tanenhaus, 1964: p. 49). Each formal discipline gradually becomes unknown in its entirety. No theory can any longer encompass the whole territory of a discipline. Talcott Parsons was the last sociologist to attempt such a theory. As a discipline grows, its practitioners become specialized and must neglect other areas of the discipline. It is for this reason that scissiparity, the amoeba-like division of a discipline into two, is a common process of fragmentation. Specialization provides researchers with methods so that they need not develop them anew. Refinements in methods are more easily transmitted among specialists. Specialization within disciplines is visible in national and international professional meetings. Everyone who has participated at a gathering of several thousand people has noticed the absence of coherence: 20–30 panels may run simultaneously, most of them mobilizing only a handful of people. The plenary sessions attract only a small minority, with most participants uninterested in issues encompassing the entire discipline.

Disciplines fragment along substantive, epistemological, methodological, theoretical, and ideological lines. To those in the field, the theoretical and ideological divisions are likely to seem more important than to others. Ralph Turner gives a description of this process in sociology, based on his experience as Editor of an important journal: "In the 1930s and

1940s the aspiration to be a general sociologist was still realistic. There was a sufficiently common body of core concepts and a small enough body of accumulated research in most fields of sociology that a scholar might make significant contributions to several, and speak authoritatively about the field in general. It is difficult to imagine the genius necessary for such accomplishments today" (Turner, 1991: p. 70).

The division of disciplines into specialties should be distinguished from their fragmentation into schools and sects. The term school refers to a group of scholars 'who stress a particular aspect.' The proponents of a school are emotionally committed to their approach. A school is simultaneously a subdivision of a field and a species of cult or sect (Smelser, 1967: pp. 6–7). While the multiplication of specialties is related to the maturation of the discipline, "the presence of numerous schools in a discipline generally be tokens a relative scientific immaturity" (Smelser, 1967: pp. 6–7). The same diagnosis is formulated by Gabriel Almond who, by crossing two dimensions, an ideological one and a methodological one, described four types of schools in political science (Almond, 1990: p. 15). These types are not determined by the process of specialization.

Various authors stress the importance of the patrimony's expansion for subsequent fragmentation. As disciplines grow, they fragment and most parts become the patrimonies of individual subfields; a rare few are passed down in the patrimony of several formal disciplines and become the classics. For Randall Collins, the increasing specialization in sociology could be explained by the growth in scale in the profession during the late twentieth century: "How does one make oneself visible when the sheer number of competitors increases? The field differentiates into various specialties. Instead of seeking recognition in the larger field, one opts for a smaller arena within which the discourse and the search for originality and for allies can go on" (Collins, 1986: p. 1340). A process of differentiation without integration is visible across disciplinary borders. Specialists "seem scarcely to recognize the names of the eminent practitioners in specialties other than their own" (Collins, 1986: p. 1340).

Another scholar who emphasizes the importance of specialties in the organization of scientific communities is Harriet Zuckerman: "Much historical and sociological evidence suggests that specialties have been prime audiences for many scientists: they are the explicit and tacit audiences – the reference groups – to which they address their work, just as they are the prime sources of wherewithal and rewards for that work" (Zuckerman, 1988: p. 539). As in some cathedrals, there are more ceremonies in the chapels than under the principal nave.

Specialties versus Disciplines

Analyzing the relationships between specialties *within* disciplines and between specialties *across* disciplines, two kinds of disciplines can be perceived: "restricted disciplines, such as most physical sciences, which would be expected to exhibit a high degree of linkage between different research areas within the discipline, but less linkage to other disciplines," and unrestricted sciences, such as most social sciences, which would be likely to exhibit relatively diffuse links among research areas both within and outside the disciplines (Crane and Small, 1992: p. 200).

Depending on the definition we adopt, there are in the social sciences between 12 and 15 formal disciplines, but dozens of specialties, sectors, fields, and subfields. In sociology, for instance, there are some 50 specialties, as indicated by the list of research committees of the International Sociological Association. There are as many in the International Political Science Association. Most of these groups cooperate to a limited extent within their respective discipline.

There is more communication between specialties belonging to different disciplines than between specialties within the same discipline. Sociometric studies show that many specialists are more in touch with colleagues who belong officially to other disciplines than with colleagues in their own discipline. The 'invisible college' described by Robert Merton and other sociologists of science is an eminently interdisciplinary institution because it ensures communication not only from one university to another and across all national borders, but also, and above all, between specialists attached administratively to different disciplines. The networks of cross-disciplinary influence are such that they are obliterating the old classification of the social sciences.

The division of disciplines into subfields tends to be institutionalized, as can be seen in the organization of large departments in many American and European universities. Another good indication of the fragmentation of the discipline is the increasing number of specialized journals. In the last two decades several hundred specialized journals in English relevant to social sciences have been launched. Most of these new journals cross the borders of two or three disciplines. Some other new journals have appeared in French and German. European unification has had an impact on the development of cross-national journals focusing on special fields. Specialization has consequences on the role of national professional associations and on the general journals. The size of specialties varies greatly: Egyptology and biosociology are small specialties; socialization and clientelism are very large. A segment which drifts away from the main body of the discipline has to reach a certain critical size before being recognized. Some of them enjoy a relative autonomy within the discipline.

A distinction has to be drawn between specialization within a formal discipline and specialization at the intersection of several monodisciplinary subfields. The latter can occur only after the former has become fully developed.

Recombination of Specialties across Disciplines

Specialization within disciplines, accompanied by their fragmentation, is the first process. Recombination of specialties across disciplinary borders is the second. In the history of science a twofold process can be seen: on the one hand, a fragmentation of formal disciplines and, on the other, a cross-disciplinary recombination of the specialties resulting from fragmentation. The new field may become independent, like social psychology, or may continue to claim a dual allegiance, like historical sociology. In the latter case, librarians are not

sure whether to place a work in the category of history or of sociology.

Such a recombination has been called hybridization (Dogan and Pahre, 1990: p. 63). A hybrid is a combination of two branches of knowledge. Jean Piaget suggested a different analogy: genetic recombination (Piaget, 1970: p. 524). The reasons for hybridization are clear enough: specialization leaves gaps between disciplines; specialties fill the gaps between two existing fields. Many of the new specialties are to a large degree hybrid specialties. The phenomenon is even more obvious in the natural sciences, e.g., in the awards of the Nobel prizes.

Some scholars recommend an 'interdisciplinary' approach. Such a recommendation is not realistic because it overlooks the process of specialization. Research enlisting several disciplines involves in fact a combination of segments of disciplines, of specialties, and not whole disciplines. The fruitful point of contact is established between sectors, and not along disciplinary boundaries. Considering the trends in the social sciences, the word 'interdisciplinarity' appears inadequate since it carries a hint of superficiality and dilettantism, and consequently should be avoided and replaced by hybridization of specialties. Different disciplines may proceed from different foci to examine the same phenomenon. This implies a division of territories between disciplines. In contrast, hybridization implies an overlapping of segments of disciplines, a recombination of knowledge in new specialized fields. Innovation in each discipline depends largely on exchanges with other fields belonging to other disciplines.

When old fields grow they accumulate such a mass of material in their patrimony that they split up. Each fragment of the discipline then confronts the fragments of other fields across disciplinary boundaries, losing contact with its siblings in the old discipline. A sociologist specialized in urbanization has less in common with a sociologist studying elite recruitment than with a geographer interested in the distribution of cities; the sociologist studying social stratification has more in common with his colleague in economics analyzing income inequality than he does with a fellow sociologist specialized in organizations; psychologists studying child development are much more likely to be interested in developmental physiology or in the literature on language acquisition than they are in other branches of psychology. A political scientist researching political socialization reads more sociological literature on the agents of socialization (family, church, school, street-corner society, cultural pluralism, etc.) than literature in political science on the Supreme Court, legislative processes, party leadership, or the recruitment of higher civil servants. Those working on the subfield of international relations in the nuclear age have little recourse to the classical literature in political science, but rather to economics, technology, military strategy, diplomatic history, game theory, nuclear physics, and engineering.

Most hybrid specialties and domains recognize their genealogical roots: political economy, political sociology, social geography, historical sociology, genetic demography, psycholinguistics, social anthropology, social ecology, biogeography, and many others. Some hybrid sciences do not indicate their filiation in their name: cognitive science, paleoarcheology. Eight social sciences also have roots in the natural sciences: demography, geography, psychology, anthropology, linguistics, archeology, criminology, and cognitive science. The hybrid specialties branch out in turn giving rise, at the second generation, to an even larger number of hybrids.

Recombination of specialties appears in the borrowing of concepts, theories, and methods (Dogan, 1996). Concepts are vehicles for communication between specialties belonging formally to different disciplines. Concepts are not equally important in all specialties. For instance, alienation is more frequently used in social psychology than in political economy, segregation more in urban studies than in comparative politics, and charisma more in political sociology than in social ecology.

There are very few general theories accepted by the majority of scholars in any discipline; the best known theories are specialized theories: they are what Robert Merton calls middle-range theories, which do not encompass an entire discipline, but only a part of it. A specialized theory can cross several disciplines with a minimal effort of adaptation. For instance 'rational choice' – considered by some as a theory and by others as a school or sect – is, except for some stylistic features, basically the same in political science, in sociology, and in economics. The theory of methodological individualism does not change on moving from one discipline to another. Two to three dozen theories peregrinate freely among formal disciplines. The high interdisciplinary mobility of specialized theories and of specialized concepts, and also of research methods, gives some centripetal orientation to the wide range of social sciences. The cross-disciplinary diffusion of concepts and theories is in fact a diffusion among specialties belonging to different disciplines.

Methodology divides some disciplines as much as ideologies, and at the same time builds bridges between specialties across the disciplinary borders. The scholars who practice factor analysis understand each other well no matter what their official disciplinary affiliation, but most of them encounter some difficulties in communicating, *within* their discipline, with their colleagues who do not practice quantitative methods. In some departments methodological controversies generate factions, which may or may not coincide with divisions between specialties.

The citation patterns in academic publications permit us to measure empirically the degree of coherence of a discipline, the relations between specialties within disciplines, and the interferences of disciplines. If specialists in a given subdiscipline tend to cite mostly, or exclusively, specialists of the same subdiscipline, and if relatively few authors cite across the borders of their subdiscipline, then the formal discipline presents a low degree of internal coherence. In this case the real loci of research are the specialties. If, on the contrary, a significant proportion of authors cross the borders of specialties, then the discipline as a whole appears more or less as an integrated territory (Dogan, 1997). Political scientists have borrowed in the 1930s from law, in the 1950s from sociology and law, and in the 1970s from sociology, philosophy, economics, history, and psychology. According to Craig Calhoun, "Sociology is neither the most open nor the most insular of social sciences" (Calhoun, 1992: p. 143). A study of patterns of citation during the period 1936–75 has found that sociologists cited 58% of the time articles in sociology journals, political scientists cited 41% of the time scholars from their own discipline, anthropologists referred 51% of the time to their colleagues, psychologists 73% to their own kin, and 79% of the

economists did the same (Rigney and Barnes, 1980: p. 117). In each social science a significant proportion of theoretical, methodological, and substantive communication has been with other disciplines, the most open being, in the late twentieth century, political science and the most autarchic economics.

In an analysis of journals identified as belonging to sociology and economics, a significant shift has been found from sociology to 'interdisciplinary sociology' and from economics to 'interdisciplinary economics,' between 1972 and 1987. The criteria for trade between disciplines was the proportion of citing references in journals of the respective discipline (Crane and Small, 1992: pp. 204–205). An analysis by the same authors in terms of clusters of references shows a clear increase in interdisciplinary relationships.

Most social scientists are specialists contributing primarily to their own subdiscipline. For instance, the *Handbook of Sociology* edited by Neil Smelser (1988) is divided into major specialties, without an overarching structure. Smelser is aware of this heterogeneity. Noting that Talcott Parsons had 'exaggerated the internal unity of the discipline,' which 'if applied today would appear almost ludicrous' (p. 12), he writes: "there appears to be no present evidence of an overarching effort at theoretical synthesis … and little reason to belief that such an effort is on the horizon," adding that "we have by now gone too far down the road of specialization and diversification" (p. 12). The ship of sociology is already built with watertight compartments. If the borders between specialties *within* disciplines are hermetic, in exchange, paradoxically enough, the frontiers between formal disciplines are open.

A distinction is needed between interdisciplinary amalgamation and hybridization by recombination of specialties belonging to different disciplines. A 'unified social science' was visible only in the early phase of the development of social sciences, when disciplines were not yet differentiated. Hybridization of specialties came much later, after the maturation of the process of internal fragmentation of disciplines. The word interdisciplinary is appropriate only for a certain phase of social sciences at the beginning of the twentieth century; it becomes misleading when it is used to describe contemporary trends, because at the end of the twentieth century only specialties are overlapping, not entire disciplines.

Some may confound recombination and synthesis. A synthesis brings a new interpretation, a personal or stylistic achievement. The difference is most clear in history. Arnold J. Toynbee's theory of history and Hobsbawn's *The Age of Empire* are syntheses. Fernand Braudel's *The Mediterranean World* is a recombination of segments of social sciences, largely history and geography. Perry Anderson's *Lineages of the Absolutist State* is largely synthesis, whereas Karl Wittfogel's *Oriental Despotism* is largely recombination. The recombinations are varied. Child development includes developmental physiology, language acquisition, and socialization. Indo-European studies encompass segments of historical linguistics, archeology, prehistory, and botany. Scholars in criminology come from subfields in law, sociology of deviance, social psychology, endocrinology, urban studies, social economics, and ethnopolitics. The study of artificial intelligence encompasses formal logic from philosophy, grammar and syntax from linguistics, and computer programing from computer science. Folklore studies include sectors from historical linguistics, cultural anthropology, social history, and comparative literature.

In one generation the number of social scientists has increased 10-fold. Their status in the profession depends mostly on their contribution to knowledge, and much less on their performance as teachers. As teachers they are generalists, as researchers, specialists. A strong feeling of diminishing marginal returns is perceived among the mass of social scientists. This phenomenon of saturation and overcrowding has been called the 'paradox of density': the tendency of densely populated disciplines to produce less innovation per head in spite of the greater effort applied in these overcrowded domains (Dogan and Pahre, 1990: p. 32). What is perceived by some scholars as 'dispersion' and 'disintegration' should be considered as manifestations of the growth of specialties, resulting in the weakening of the saturated disciplinary core, a process engendered by centrifugal and autonomous tendencies of the specialties across disciplines. The recombination of specialties across disciplines requires a remodeling of the intellectual map of the behavioral social sciences.

Abstract

The use of error profiles in the study of language is reviewed, with specific attention to errors made in fluent speech by normal adult speakers. These are errors of performance, not errors of knowledge – i.e., speakers use an unintended sound or word, or place an intended element in an unintended location. Such phenomena are generally referred to under the label 'speech errors' in the psychological and linguistic literature The major results of error analysis indicate a staged architecture for sentence generation in which meaning, syntax, and sound representations are successively integrated. Speech error modeling converges in most major respects with the results of experimental studies of language generation.

The generation of spoken language is a complex task normally accomplished with high accuracy. Human beings are, on average, consummate 'talkers.' But, speakers do err occasionally, and in ways that reflect the mental processes underlying the act of speaking. That is the topic pursued here: What are the speech error patterns of normal language use, and what do they tell us about language processing?

Various departures from the ideal of perfectly articulated, fluent speech occur in ordinary conversation: hesitations, false starts, changes of mind in mid-sentence, and misarticulations. These have their own interest, but are not the focus of this discussion. The term 'speech error' has come to be used in a semitechnical fashion to pick out particular types of errors from the welter of everyday language. The targets are those fluently uttered forms in which some element or elements of the intended utterance are missing, mis-selected, or misordered. Speakers often, though not invariably, notice and correct these failures. Errors arising from ignorance of a word or of 'proper usage' and various nonfluencies are thereby distinguished from speech errors from this perspective.

Attention to speech errors has a long history ranging from the exploitation of their humorous potential ('Spoonerisms') to their recruitment for systematic scientific study. Many different investigators have contributed to this area, and the scientific purposes to which such data have been put are diverse, including both structural linguistic interpretation and psychoanalytic interpretations in the nineteenth and early twentieth century, and more recently, interpretation for modeling real-time language use. In this latter exercise, the collection and interpretation of speech errors strongly affected the initial framing of contemporary models of language production, and is systematically linked to the development of a number of experimental paradigms currently used to study production processing.

A Methodological Note

How is error data acquired? Several investigators have collected extensive records of errors heard during everyday language use. A classic such effort was that of Rudolf Meringer (Meringer and Meyer, 1895) in the late nineteenth century. Cutler and Fay (1978) describe his methods in their introductory essay to a reissue of Meringer's work. The practices they describe are characteristic of later diary studies. Typically, a written record of an error is made soon after observation (normally, a few seconds to a few minutes), with annotations regarding pronunciation and setting. Such observation has the strong appeal of face validity for processes of language formulation. However, influences of perceptual filtering and memory distortion must be carefully weighed. It is clear that minor phonetic deviations may be missed, and only changes clearly discernable with respect to the speaker's target are well represented in such error corpora. See Cutler (1982) for detailed discussion of these and related issues.

Diary studies exist for several languages. It may be said with some assurance that whether the target language is Chinese, Dutch, English, German, Italian, Spanish, Turkish, or other, the same general types of phenomena arise. Specific language features may afford options for error – e.g., Chinese tone errors – not available in English or related languages. Nevertheless, the general behavior of errors involves similar mechanisms across languages. Discussion here focuses on English, with some commentary on representative language differences. Error examples are taken from papers in the bibliography.

Types of Error

In the popular literature, 'speech error' is synonymous with 'Spoonerisms,' named after the Dean of New College, Oxford, Rev. W.A. Spooner (1844–1930), who was notorious for his frequent misplacements of speech sounds, sometimes to extraordinary effect. For example, in lecturing a wayward student, he is alleged to have said: "You have hissed all my mystery lectures. … and tasted two worms" ("missed all my history lectures … wasted two terms"). But Spoonerisms are special in several respects. They suggest that sound errors usually make words, and that they make a kind of wild and humorous sense. Neither condition is typical. Furthermore, Spoonerisms primarily exploit sound error, and the relevant phenomena are much more general. No account of Rev. Spooner's performance is given here; for comment, see, e.g., Robbins (1966).

Notwithstanding the exclusion of Rev. Spooner's legacy, there is no denying the charm of suitably chosen errors as a way to display the hidden structure in language. The errors are intricate, and they illustrate essential features of language processing. Examples (1)–(14) are representative:

1. '…sat down on a *s*ot *h*oddering iron' (…hot soldering…)
2. 'I won't hit the ba*rd* ha*ll*' (…ball hard)
3. 'I have a case of l*ay* gr*o*de flu' (…low grade…)
4. '…so I can start the s*tape* back up (…the tape…)
5. 'The curren*th* month is… (The current…)
6. '…an anguage *l*acquisition device… (…a language acquisition…)
7. 'Is your *purr*y *kitt*ing' (…kitty purring)
8. 'Make it so the *apple* has less *tree*s (…so the tree has less apples.)
9. 'She *sings* everything she *writes* (…writes everything she sings)
10. 'Bensinger takes to that left-field wall like *water* takes to *a duck* (…like a duck takes to water)
11. 'I've got whipped cream on my *mushroom*! (…on my mustache!)
12. 'You put your *nose*… your finger on it (…put your finger on it)
13. 'My! So that's the Porche *symblem* (symbol/emblem)
14. '*It doesn't care* (It doesn't matter/I don't care).

A rough task analysis sets the stage for interpretation of such errors. It is evident that systems for speaking will necessarily include mechanisms that select from tens of thousands of available words just those appropriate to an intended message ('lexical retrieval'), mechanisms that integrate the words into sentence structures ('syntactic construction'), and mechanisms that orchestrate the result of those operations into control structures ('phonological and prosodic integration') that drive motor outputs (articulation). Psychological explanation must reconstruct this complex of mental events.

Descriptively, in examples (1)–(7), sounds move around in various ways – they are exchanged anticipated, perseverated, and shifted. Important features of sound error include the following: Moved elements are *phonetically similar*, they correspond in *syllabic position*, and their immediate *phonetic environments are similar* (Boomer and Laver, 1968; Dell, 1984; Nooteboom, 1969; Caldognetto et al., 1987; del Viso et al., 1991; McKay, 1970; Vousden et al., 2000). The fact that error likelihood is so strongly influenced by similarity of structural environment suggests that errors arise, in part, out of mechanisms that associate independently specified processing elements (sounds, in this example) with a *planning framework* ('syllable or word frames,' in this instance). These errors and related phenomena indicate how sounds that make up words enter planning structures for sentences. In the task analysis, this reflects phonological and prosodic integration processes.

Examples (8)–(10) are 'word movement' errors. Some are of special interest because they reflect an analysis of words into stem and affix. In Example (8), 'apples' is decomposed into 'apple + s' – more abstractly ['apple' + plural marker]. The technical term in linguistic science for such a decomposition is morphemic analysis. Notice that the two types of morpheme (stem and affix) behave in very different ways. The stem moves, but the affix stays behind. One can also describe this error in terms of the notion of structural frame. By this hypothesis, the affix would be considered part of a phrasal frame that stem morphemes are assigned to as a sentence develops. This idea proves applicable to a wide range of error observations, and is strikingly manifest in languages with richly developed morphological structures. (Related facts are discussed in Section Generalizing the Observations about Processing Frames.) In the task analysis, these errors implicate syntactic integration.

Examples (11) and (12) provide another perspective on errors. Descriptively, these are *word substitutions*. Several points are relevant. First, (11) displays a phonetic similarity between target and intruding element; the phonetic similarities between 'mustache' and 'mushroom' are representative. Moreover, both words are nouns. Thus, the syntactic structure of the intended utterance is preserved. One may plausibly treat this as a failure – perhaps triggered by phonetic similarity – of mechanisms that retrieve elements from an inventory of word forms. But what about errors like (12)? Grammatical category is preserved, but phonetic similarity is not apparent. Quite unlike (11), an obvious meaning relation holds between target and intrusion. Section Lexical Selection Processes: Word Substitutions discusses this contrast. In the task analysis, these errors implicate lexical selection processes, and they encompass both form and meaning relations.

Examples (13) and (14) are *blend* errors. In word and phrase blends, two processing elements compete for a *single output slot*. Speakers are often aware of the competition and can report experiencing it. The competing expressions are, with rare exception, of the same grammatical class and are semantically equivalent for the intended message. This phenomenon is a prima facie demonstration of some parallelism in sentence production. Such errors implicate lexical selection processes and aspects of phrasal and phonological composition.

Interpretations of Error Phenomena

Speech errors have many variants. The challenge is to explain their similarities and differences in ways that link them to accounts of production mechanisms at the necessary levels of representation (phrases, words, morphemes, syllables, sounds). A robust generalization across the error types is relevant: Like elements interact, i.e., sounds interact with sounds, words with words, and phrases with phrases. These interactions indicate vocabularies of 'units,' and the error data shows they are linked in an architecture of processing stages discussed in Sections Accommodations in Error Processes–Generalizing the Observations about Processing Frames.

Accommodations in Error Processes

Errors move elements of the intended utterance to 'new' positions. Because languages display many local dependencies of form, such displacements could violate these. But, typically they do not. Example (6) illustrates: '*a* language acquisition device' became '*an* anguage lacquisition device.' The indefinite article changed from 'a' to 'an,' and so *accommodated* to the vowel onset ('anguage') created by the error. In Example (14), the bound morpheme derives 'easily' from 'easy' shifts. But, the resulting isolated stem 'easy' was correctly pronounced

as /izi/ rather than with a reduced final vowel (as would have been appropriate had the affix remained in place).

15. '… *easy enoughly* …' (easily enough)

Many such variations triggered by changes in phonetic context appear in accommodations. By these observations, processes that fix the surface forms of words are ordered later than the error-generating structures and associated operations: First, an abstract morphological and phonological representation is constructed and then regular processes flesh out its phonetic detail. This is a familiar notion in linguistics, and its expression in error phenomena is not greatly surprising (see Fromkin, 1971). But, bear in mind that it could have turned out otherwise. The speaker of Example (6) might have said 'a anguage' but did not; the speaker of Example (15) might have said 'easuh enoughly,' but did not; and so on. Error processes on this evidence are tightly bound to the structural systems that govern error-free speech.

Other Evidence for Ordering of Processes: Sound Exchanges and Word Exchanges

These error classes reveal syntactic and phonological planning structures. Sound interactions, and particularly exchanges as in (1)–(3), typically involve words in the same phrase. The relevant structure is prosodic (see Boomer and Laver, 1968; Fromkin, 1971; Garrett, 1980). Prosodic grouping reflects syntax, but is also motivated by intonation and the phonological structure of the words chosen to express a given syntactic form. Treating the domain of sound exchange as prosodic may also explain some cross-language differences. For example, sound exchanges in English are predominantly between words, but in Spanish, within words (del Viso et al., 1991). The greater morphological complexity and length of Spanish words, as compared to English, would require exchanges between words to cross prosodic boundaries more often for the former than the latter.

Word and phrase exchanges sharply differ from sound exchanges. As Examples (9), (10), and (16)–(18) suggest, they arise for elements in distinct phrases that correspond in grammatical category

16. '… I left my *briefcase* in the *cigar*' (… my cigar in the briefcase)
17. 'What we want to do is train *its tongue* to move *the cat*' (… the cat to move its tongue)
18. 'As you *reap*, Roger, so shall you *sow*' (As you sow … so shall you reap)

Nouns exchange with nouns, verbs with verbs, adjectives with adjectives (Bierwisch, 1970, Garrett, 1975; Nooteboom, 1969). On this evidence, operations at the point of error involve the grammatical roles of words (or minimal phrasal units). Bear in mind that sound exchanges differ from word exchanges in both respects. Recall also that sound exchanges implicate many detailed features of phonological structure, whereas word exchanges are minimally so affected (see Dell and Reich, 1981; del Viso et al., 1991). These differences in the role of phrasal domain, grammatical category, and phonological description suggest two processing systems. Syntactic constituents are built by a multiphrasal processor that does not represent the sound structure of its elements (i.e., of word stems, morphemes, simple phrases); failures yield word and phrase exchanges. A subsequent process then elaborates sound sequences for words within a phrase group; failures yield sound exchanges. Multiple phrasal units are present at the syntactic level, and a narrower planning window develops sound structures and pronunciation codes in prosodic groups.

Stranding Errors and Multiple Levels of Processing

The exchanges in Examples (7) and (8) decompose target words into their constituent morphemes and strand affixes. One finds stranding of a variety of productive structural markers, predominantly those of inflectional device (e.g., number, tense, and aspect markers, gerundives, comparatives). Evidence indicates that stranding arises at two points: within phrase (re prosodic groups for sound exchanges), and between phrase (re structures for word exchanges) (see Garrett, 1993). These ideas extend the earlier discussion of accommodation. That discussion described it as a phonologically conditioned response to error movements. But, consider Examples (19) and (20)

19. '…that I would *hear* one if I *knew* it' (…that I would know one if I heard it)
20. '…drei *Wochen* im *Tag* gearbeitet' (drei Tage in der Woche gearbeitet).

Here there is accommodation, but, strikingly, it involves irregular forms of inflected words. In Example (19), the appropriate irregular verb forms for 'know' and 'hear' appear. The German example (Bierwisch, 1970) shows several accommodations. Singular '*Woche*' takes plural marker 'en'; plural '*Tage*' has the singular form '*Tag*.' Further, German nouns bear grammatical gender: '*Woche*' is feminine, '*Tag*' is masculine. The articles required thus differ, and may interact with prepositions. Here, number and gender are indeed appropriate, including interaction with the preposition ('*im*' is a contracted form of '*in dem*').

What accounts for this impressive range of accommodations for these error types? They are lexically dependent and so not derivable from phonological environments (as described in Section Other Evidence for Ordering of Processes: Sound Exchanges and Word Exchanges). In fact, lexically dependent accommodation occurs predominantly for between phrase stranding exchanges for elements of corresponding grammatical category. In the account sketched in Section Other Evidence for Ordering of Processes: Sound Exchanges and Word Exchanges, such errors must occur earlier than sound errors – at the level of abstract phrasal construction, prior to the phonological interpretation of content words. Development of the irregular forms then follows from affiliation of the switched stems with stranded inflectional features.

Generalizing the Observations about Processing Frames

Stranding shows that inflectional elements are separately represented when stems are inserted into phrasal frames. This can be expressed by assuming that inflectional elements are parts of structural frameworks. If exchanges arise when lexical elements are misassigned to structural frames, it follows that parts of frames should not exchange. This expectation is borne out in

error corpora; inflectional exchanges are rare (Garrett, 1975; Stemberger, 1985). Another class of observations (morpheme shifts), not discussed here, may also be connected to this picture (see Garrett, 1980).

There is some basis for treating all functional elements both bound and free in this way. The claim is that functional elements (inflections, determiners, complementizers, etc. – the minor grammatical categories) are derivatives of structure and are thus recruited for incorporation into sentences by different mechanisms than those responsible for the selection of content items (nouns, verbs, prepositions, adjectives, adverbs – the major grammatical categories). This contrast has been discussed in the processing literature under the label of 'open class' and 'closed class' vocabularies. It might be construed as a distinction between those elements individually selected under conceptual control ('content elements') and those that are reflexes of the logic and syntax of the sentence (Levelt, 1989; Bock and Levelt, 1994). See Myers-Scotton and Jake (2001), for a related account based on 'code-switching' (a bilingual language practice that fluently combines elements from two languages into a single utterance). Note, however, that some accounts of speech error link profiles for these vocabulary types to their relative frequency of occurrence in the language (Stemberger and McWhinney, 1986; Dell, 1991). On this view, very high-frequency rates, rather than structural roles, govern error behavior of functional elements.

Lexical Selection Processes: Word Substitutions

Word substitutions provide a data class distinct from movement error. These reflect failures in lexical retrieval; Examples (21)–(25) illustrate

21. 'Are you left-handed? No, I'm amphibian, no, ambivalent… arghh, ambidextrous!'
22. 'If you can find a *garlic* around the house, I'll take it' (gargle)
23. 'All I want is something for my shoulders' (elbows)
24. 'He rode his bike to school *tomorrow*' (yesterday)
25. 'Yumm, are we having *lobsters* tonight?' (oysters)

A dissociation of errors with meaning similarities and those with form-based similarities is immediately apparent. Fay and Cutler (1977) in a seminal paper described these contrasts and proposed two selection processes, rooted, respectively, in content (semantic representations) and form (morphological and phonological representations). Depending on which process is compromised, errors should display quite different similarity metrics. Fay and Cutler's analysis, and subsequent studies, revealed multiple systematic form relations between target and error words that lacked a meaning relation – as Examples (11), (21), and (22), while errors with meaning relations, as in Examples (13), (23), and (24), lack such striking phonological resemblances.

These substitutions also interact with sentence structure: Grammatical category correspondence between target and intrusion powerfully constrains word substitutions whether semantically or form driven. This links to the movement error analysis in Sections Accommodations in Error Processes–Generalizing the Observations about Processing Frames. That analysis indicates staged processing in which phonologically uninterpreted elements are first associated with syntactic environments, followed by assignment of phonological representations to structural frameworks. Word substitution patterns of the sort just described therefore fit well into those structural processes. The distinction parallels the discussion of lemmas in Speech Production, Psychology of. Meaning-guided retrieval selects lexical representations (phonologically uninterpreted: lemmas) for input to the multiphrasal construction process that is the locus of word exchanges. Following this, word form retrieval (mapping from lemmas to word forms) provides inputs to the prosodic groups that are the locus of sound exchange errors.

The ordering is clear, but details of the sequencing less so. The differences between meaning and form-based substitutions have been a matter of sustained debate. A way to put this is to ask whether semantic selection is accomplished without feedback from form to meaning levels. Dell (1986) and others have argued that the process is to some degree interactive, and includes such feedback, yielding semantically related errors that also display a degree of form relation, as illustrated in Example (25). Such errors are a minority, but occur with greater than chance likelihood. See Dell et al. (1997) for a relevant review.

What Causes Error?

Several causal factors have been identified. Broadly speaking, they are either 'noise' or 'competition' based. See Butterworth (1982) for a helpful exposition. He distinguishes causes of error in terms of 'sentence internal' and 'sentence external' processes, with emphasis on 'competing plans' as error sources.

Fluctuations in efficiency of the neural systems that underlie language processes could clearly cause error. But such accounts require explicit linkage to production mechanisms. This step is well represented in work by Dell (1986) and others using network models to simulate error patterns; see also Levelt et al. (1999). Error caused by competing sentence formulations is also readily identifiable in blends – as in Examples (13) and (14). These give strong evidence for multiple encoding paths within a sentence. It is easy to generalize such conditions to rationalize certain word substitutions and sound errors as well.

'Sentence external' processes provide additional sources of competing expressions. Such may be discourse-relevant variations on sentence form or discourse external representations for an independent line of thought. This latter may also include interaction of linguistic processing with attentional mechanisms that filter automatic responses to the environment. A 'filtering breakdown' may lead to incorporation of environmental material into speech (see e.g., Harley, 1990).

Sigmund Freud (1901) is identified with accounts of errors motivated by thoughts related to unconscious wishes and desires. His account links those thoughts to the meaning of the words or phrases resulting from error. That requirement suggests that Freudian mechanisms are not a major factor in the generation of movement errors of the sort discussed here. A robust feature of virtually all such errors is their indifference to the meaning of error products (Bierwisch, 1970). An alternative focus for Freud's claims may lie in editorial

processes – i.e., accounts of self-monitoring and its relation to the mechanisms of sentence production (see Motley et al., 1982).

The Broader Picture: Building Models of the Language Production Process

Speech error analysis provides a rich source of information about the real-time processes that underlie human abilities to generate fluent, coherent, oral discourse. But, rich as it is, there are sharp limitations on its utility for certain questions about language production. Issues of semantic and discourse structure are awkwardly represented or absent from error data, and multiple questions about the temporal relations of lexical and phrasal integration are undetermined by the patterns of naturally occurring speech error. In particular, issues surrounding the potential interdependency of the staged processes described here are difficult to assess on error data alone. At precisely this point one turns to experimental studies of production performance.

Bock and Levelt (1994) provide a synthesis of several strands of production experimentation and points of integration with speech error patterns. A number of areas of experimental enquiry have afforded noteworthy elaborations of production theory. Bock (1987, 1990, 1995) and collaborators used picture description tasks and related techniques to uncover detailed relations between sentence generation and the underlying conceptual structures that sentences encode. Models of lexical retrieval have been extensively investigated via picture naming and related paradigms (*see* Speech Production, Psychology of). Experiments that focus on TOT (tip of the tongue) states provide complementary information on lexical staging for syntactic and phonological representations (see, e.g., Badecker et al., 1995; Vigliocco et al., 1997). Studies using error induction techniques also provide points of contact with spontaneous error data. See Shattuck-Hufnagel (1987) for a comprehensive series of error induction studies relating sound error to lexical and phrasal structure, including stress factors. Work by Baars et al. (1975) led to a series of investigations showing lexical influences on the probability of sound exchanges. Some aspects of the experimentation point to monitoring processes as the source of such effects (see Levelt et al., 1999 for review). An extensive experimental literature on induced agreement errors evolved from the original work by Bock and Miller (1991) on English number agreement (see Eberhard et al., 2005 for a synthetic review). Cross-linguistic study of agreement issues has been a significant component of this class of studies (see, e.g., Vigliocco et al., 1996). An expanding area of research activity in the last decade has focused on morphological processes. Such structure is extensively implicated in speech error patterns. For a systematic casting of speech error patterns that addresses morphological issues within a specific formal linguistic framework, see Pfau (2007). There is a substantial range of experimental work exploring effects of morphology in both comprehension and production. See Luttmann et al. (2011) for a recent experimental examination of lexical retrieval processes in production and their interaction with the semantic features of morphologically complex words.

Speech Perception

Dominic W Massaro, University of California Santa Cruz, Santa Cruz, CA, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

This psychological account of speech perception includes a description of the stimulus variables that support it and the internal processes that account for it. Research and theory indicate that speech perception is a form of pattern recognition that is influenced by multiple sources of bottom-up and top-down information.

Speech Perception warrants an entry in this encyclopedia along with Motion Perception and Music Perception. One possible implication of a separate entry for Speech Perception is that it differs significantly from other types of perceptions. In fact, much of the six or seven decades of research and theory centered on this topic has assumed that speech is special. If speech is special, then how it is perceived must also be special. In many ways, the specialty assumption is congruent with the more prominent belief that language and how it is acquired is special.

Speech Is Special

A highly influential proposal by Noam Chomsky envisioned language ability as dependent on an independent language organ (or module), analogous to other organs such as our digestive system. This organ follows an independent course of development in the first years of life and allows the child to achieve a language competence that cannot be elucidated in terms of traditional perception and learning theory. This mental organ, responsible for the human language faculty and our language competence, matures and develops with experience, but the matured system does not simply mirror this experience. The language user arrives on this planet with rule systems of a highly specific structure capable of acquiring languages that necessarily have a structure corresponding to these rules. This innate knowledge is necessary to become an expert in using language, even though the typical child has a paucity of the language input. The data of language experience are so limited that no learning process of induction, abstraction, generalization, analogy, or association could account for our observed language competence. Somehow, the universal grammar given by our biological endowment allows us to learn to use language appropriately without learning many of the formal intricacies of the language. This theory is highly controversial and there are many reasons to remain skeptical. As counterevidence, psychologists are demonstrating that infants' language is highly influenced by typical perception and learning processes, and linguists are documenting that the child's language input is not as sparse as the nativists claim (Scholz and Pullum, 2006).

Luckily for our purposes, we can evaluate the claim that speech is special without resolving the language is special controversy. There are several aspects of speech that appeared to demand specialty status. Perception researchers typically expect an orderly relationship between a stimulus and its resulting percept. The loudness of a tone increases as it is increased in intensity, for example, and two different intensities would give different percepts. However, the speech percept appeared to be characterized by a non-invariant relationship between it and the eliciting stimulus. An historical example gives the surprising perception of consonant–vowel (CV) syllables /di/ as in deed and /du/ as in do. We hear the phoneme (Smallest segment of spoken language that is functional in communicating meaning.) /d/ in both cases, but the speech signal differs significantly in the two cases. Of course, not every scientist was convinced that phonemes did not have invariant signal properties in different vowel contexts, and research in the six or so decades since the original claim has continued to attempt to uncover these properties (e.g., Kapoor and Allen, 2012). Even so, no one has yet provided convincing evidence of invariance.

Faced with this conundrum, researchers looked for a solution outside of the normal framework of perception in which the goal is to describe the stimulus characteristics responsible for perceptual outcomes. An obvious alternative was to believe that a motor theory could reinstate the regularity between signal and percept. A motor theory of speech perception would assume that we somehow perceive the vocal tract gestures creating the sounds rather than the sounds themselves. As recently observed by Hickok, motor theories have a long history in behavioral science. Over 100 years ago, Walter B. Pillsbury (1911: p. 84) said "The [motor] theory is so simple and so easy to present that everyone is glad to believe it. The only question that any one cares to raise is how much of it will the known facts permit one to accept." It is sobering how little has changed in the intervening century given that many scientists have not been swayed by Pillsbury's caveat. Speech provided a natural domain for a motor theory account because speech perception and speech production appeared to be so tightly linked. The perceiver simply perceives the intended phonetic gestures of the speaker rather than the variable auditory speech. For our /di/-/du/ example, the perceiver simply recovers the interlocutor's intention to articulate /d/ in both syllables. For most of us, it is difficult to intuit how the motor theory accounts for speech perception and how it resolves the lack of invariance problem. How do we access the talker's intended articulations? (Coarticulation: Pronunciation (articulation) of a speech segment is influenced by its neighboring segments.) If we could see the talker, we would obtain a few hints, and in fact observing the talker dramatically influences what we hear. The normal view is not sufficient, however,

because much of the articulation is hidden inside the mouth. More telling is the common observation of successful phone conversations when the talkers are not visible.

What's most disappointing about motor theory is that its advocates do not offer specific testable hypotheses about how it accomplishes speech perception. Most of the explanations have taken the form of analysis by synthesis models. Given a speech event, the perceiver benefits from synthesizing possible alternatives during their processing of the speech input and somehow determining which of these possibilities is the best match. To accomplish this selection, however, the perceiver still requires access to the speech signal, and hence we have regressed back to the original challenge of understanding how the speech signal is processed.

In one of the few explicit accounts, Vihman (2002) describes how motor processes might work in speech acquisition. The infant practices canonical babbling and produces CV sequences at 6–8 months of age. This practice in production sensitizes the infant to similar input speech from their caregivers. The familiarity of CV sequences from babbling allows them to be easily recognized because they pop out of the acoustic stream. However, although these patterns would become familiar with practice and this increase in familiarity might facilitate perception, it does not mean that the motor processes involved in babbling were also functional during the infant's speech perception.

In fact, infant speech perception is much more sophisticated than what could be predicted from canonical babbling. We know that receptive language is acquired before productive language, so it is difficult to understand how motor behavior would contribute to speech perception. Motor theory does not solve the problem of speech perception. Infants understand speech well before they produce it intelligibly. Furthermore, infants are highly sensitive to the statistical properties of segmental speech input at 6–8 months (Saffran, 2003), which could not be anticipated by canonical babbling.

Roy (2011) documents 67 instances in which his son attempted to pronounce 'water' before he was able to pronounce it correctly. Many of these instances illustrate that he was able to perceive and understand the spoken word but was simply unable to produce it accurately. This scientific observation revives the anecdotal one in which a father is mimicking his son's mispronunciation of the word 'rabbit.' His son corrects his dad saying, "No dad, not rawwit, but rawwit." The son clearly could perceive the difference between 'rabbit' and 'rawwit' even though he was not able to produce the difference. Toddlers (13–15-month-olds) have few words in their productive vocabulary but can compute the relations in a spoken sentence (Hirsh-Pasek and Golinkoff, 1996). Hickok (2009) also reviews long-standing clinical findings that falsify motor theory. For example, persons with Broca's aphasia can perceive and understand speech but cannot produce it. Thus, research on language acquisition like the research and clinical findings with adults does not support motor theory.

The astute reader will notice that we have not solved the invariance problem that motivated a motor theory account. To solve the invariance problem between acoustic signal and phoneme, Massaro (1972) proposed the syllables V, CV, or VC as perceptual units in speech, where V is a vowel and C is a consonant or consonant cluster (unit of speech that is functional in speech perception). This might appear as too easy of a solution because one might argue that the bigger the unit the better. So why not assume a word, a phrase, or even a sentence as the perceptual unit? Luckily, there were other constraints on the size of the unit. The speech representing the perceptual unit must be maintained in a pre-perceptual auditory memory in order to be functional for recognition (Massaro, 1972). Backward masking experiments indicated that pre-perceptual auditory memory had a limit of roughly 250 ms, which can hold these syllables but not longer units (this assumption was built into the foundation of the model discussed in Section The Fuzzy Logical Model of Perception). Assuming that this larger segment is the perceptual unit that reinstates a significant amount of invariance between signal and percept, Massaro and Oden (1980: pp. 133–135) reviewed evidence that the major coarticulatory influences (that are responsible for the /di/-/du/ differences) on perception occur within these syllables, rather than between the syllables. Any remaining lack of invariance across these syllables could conceivably be disambiguated by additional sources of information in the speech stream.

Popular theories, such as the motor theory, will be reinvented and will evidently endure well beyond their many falsifications as we will discuss in the next section.

Mirror Neurons

The discovery of mirror neurons has apparently rejuvenated motor theories. A mirror neuron fires both when an animal performs an action and when the animal observes the same action performed by another animal (Rizzolatti and Craighero, 2004). Mirror neurons could serve as the basis for imitation and therefore for learning. Our understanding, however, is that mirror neurons cannot account for perception because they would overgeneralize. The macaque certainly experiences the difference between seeing a conspecific action and its own action, but the same mirror neurons are putatively activated by these very different events and experiences. If only the mirror neurons were responsible for speech perception, the interlocutor would not distinguish between her perception of the utterance from her production of the utterance. Thus, mirror neurons alone cannot account for perception (see Hickok, 2009; Lotto et al., 2009 for similar observations and additional critiques).

Psychophysics of Speech Perception

In any domain of perception, one goal is to determine the stimulus properties responsible for perception and recognition of the objects in that domain. The study of speech perception promises to be even more challenging than other domains of perception because there appears to be a discrepancy between the stimulus and the perceiver's experience of it. For speech, we perceive mostly a discrete auditory message composed of words, phrases, and sentences. The stimulus input for this experience, however, is a continuous stream of sound (and facial and gestural movements in face-to-face communication) produced by the speech production process. Somehow, this continuous

input is transformed into more or less a meaningful sequence of discrete events.

In a seminal paper, Miller and Nicely (1955) were interested in the acoustic properties of speech that were important for the recognition of English consonants. They asked participants to identify 16 initial consonants placed before the vowel /a/ as in father. Degradation of performance was measured under varying conditions of noise and filtering. The standard measure of performance is in terms of a confusion matrix which shows each of the responses to each of the test stimuli. One goal of this research is to determine which acoustic properties best explain the confusion matrix. The authors chose linguistic descriptors as rough indices of the acoustic properties. These included voicing (low frequency periodic energy), nasality (spectral changes caused by energy flow through the nasal tract), frication (high frequency energy), place of articulation (formant location and transitions), and duration. Although these properties were treated as binary (or trinary) linguistic dimensions, we now know that a more accurate description would be in terms of a continuous value (Massaro and Cohen, 1999). One disadvantage of these studies is that the speech signal is necessarily degraded in order to generate errors. The results may not generalize to typical situations in which the speech is not degraded.

Greenberg and his colleagues have pursued Miller and Nicely's original quest for understanding how the various acoustic properties representing linguistic features contribute to speech perception. They find that not all linguistic features are created equal. Based on systematic studies of confusion matrices in Danish, they find that the ease of resolving three features is ordered voicing, manner, and place, respectively. They also find that resolving place of articulation is highly correlated with correct consonant identification. They interpret this result to mean that resolving place of articulation is central to speech recognition. Allen (e.g., Kapoor and Allen, 2012) and his colleagues have provided some innovative techniques to assess which acoustic properties are important for speech recognition. They systematically manipulate the natural speech signal to emphasize or degrade an acoustic feature. They systematically study the burst of energy at the onset of stop consonants in the initial position. Based on their results, they conclude that the frequency range and relative intensity of the plosive burst and its temporal relationship to the sonorance of the following vowel are sufficient features for correct identification of the four stop consonants /da/, /ga/, /ta/, and /ka/. In an earlier study, they found that /ba/ is characterized by a broad band of energy in the burst. If this information is missing, the segment is confused for the consonant /v/.

The auditory speech signal is distributed across a frequency spectrum and it has been traditional to treat this spectrum as composed of independent frequency bands. These bands are putatively independent sources of information for intelligibility of the speech signal, which are important for the accepted measures, namely Articulation Index, Speech Intelligibility Index, and the Speech Transmission Index. However, this assumption is untenable as demonstrated nicely by the research of Christiansen and Greenberg (2012).

Although six decades later, there is still active controversy over the ecological properties of the speech input that are actually functional in speech perception. One issue, revived by recent findings, is whether the functional properties in the signal are static or dynamic (changing with time). Traditionally, static cues such as the location of formants (bands of energy in the acoustic signal related to vocal tract configuration), the distribution of spectral noise as in the onset of *saw* and *shawl*, (and the mouth shape at the onset of a segment) have been shown to be effective in influencing speech perception. Dynamic cues such as the transition of energy between a consonant and the following vowel have also been shown to be important. For example, research has shown that the second formant (F2) transition defined as the change between the F2 value at the onset of a CV transition and the F2 value in the middle of the following vowel is a reliable predictor of the place of articulation category (Sussman et al., 1998).

Controversy arises when research is carried out to argue for one type of cue rather than another. For example, investigators isolated short segments of the speech signal and reversed the order of the speech within each segment (Saberi and Perrott, 1999). In this procedure, a sentence is divided into a sequence of successive segments of a fixed duration such as 50 ms. Each segment is time reversed and these new segments are recombined in their original order, without smoothing the transition borders between the segments. In this fashion, the sentence could be described as globally contiguous but locally time-reversed. The authors claimed that the speech was still intelligible when the reversed segments were relatively short (1/20th to 1/15th of a second). Their conclusion was that our perception of speech was demonstrated to be primarily dependent on higher-order dynamic properties rather than the short static cues normally assumed by most current theories. This type of study and logic follows a tradition of attempting to find a single explanation or influence of some psychological phenomenon. However, most successful research in psychology is better framed within the more general framework of *ceteris paribus* (all other aspects neutral). There is good evidence that perceivers exploit many different cues in speech perception (e.g., Greenberg and Arai, 2004), and attempting to isolate a single functionally sufficient cue is futile.

There is now a large body of evidence indicating that multiple sources of information are available to support the perception, identification, and interpretation of spoken language. There is an ideal experimental paradigm that allows us to determine which of the many potentially functional cues are actually used by human observers, and how these cues are combined to achieve speech perception (Massaro, 1998). The systematic variation of the properties of the speech signal and quantitative tests of models of speech perception allow the investigator to interpret the psychological validity of different cues. This paradigm has already proven to be effective in the study of audible, visible, and bimodal speech perception (Massaro, 1998). Thus, this research strategy addresses how different sources of information are evaluated and integrated, and can identify the sources of information that are actually used.

The Demise of Categorical Perception

Too often behavioral scientists allow their phenomenal impressions to spill over into their theoretical constructs. One

experience in speech perception is that of categorical perception (Situation in which a speech stimulus is perceived in terms of its category membership rather than in terms of its surface properties.) meaning that we perceive an utterance as a specific syllable, word, or phrase. This phenomenal outcome is easily interpreted as a perceptual process that is categorical. This means that the perceptual system only has access to categorical information about the speech event rather than access to continuous information about the degree to which various events are possible. My experience, particularly now with an increasing hearing loss of high frequencies, is just the opposite. In many instances, I am stumped with a percept that fits several possible alternatives rather than one categorically. This experience is to be expected, given a large body of empirical research that reveals that speech perception is not categorical.

Using synthetic speech, it is possible to make a continuum of different speech sounds varying in small steps between two alternatives. Categorical perception has been a central concept in the experimental and theoretical investigation of speech perception and has also spilled over into other domains such as face processing (Beale and Keil, 1995; Etcoff and McGee, 1992). Categorical perception was operationalized in terms of discrimination performance being limited by identification performance. In a very influential study, Liberman et al. (1957) used synthetic speech to generate a series of 14 CV syllables going from /be/ to /de/ to /ge/ (/e/ as in gate). The onset frequency of the second formant transition of the initial consonant was changed in equal steps to produce the continuum. In the identification task, observers identified random presentations of the sounds as /b/, /d/, or /g/. The discrimination task used the ABX paradigm. Three stimuli were presented in the order ABX; A and B always differed and X was identical to either A or B. Observers were instructed to indicate whether X was equal to A or B. This judgment was supposedly based on auditory discrimination in that observers were instructed to use whatever auditory differences they could perceive.

The experiment was designed to test the hypothesis that listeners can discriminate the syllables only to the extent that they can recognize them as different phoneme categories. Although this categorical perception hypothesis can be quantified in order to predict discrimination performance from the identification judgments (Massaro, 1987), only a qualitative analysis was carried out. A rough correspondence between identification and discrimination led the authors to incorrectly conclude that discrimination performance was fairly well-predicted by identification performance. Unfortunately, there are several notable limitations in these and many similar studies. Discrimination performance is consistently better than that predicted by identification; it is possible that participants are making their discrimination judgments on the basis of identification rather than on their auditory discrimination, and it is likely that any alternative theory would have described the results equally well (Massaro, 1987).

In many areas of inquiry, a new experimental paradigm enlightens our understanding by helping to resolve theoretical controversies. Following developments in signal detection theory, we used rating experiments to determine if perceivers indeed have information about the degree of category membership (Massaro and Cohen, 1983). Rather than being asked for categorical decisions, perceivers were asked to rate the stimulus along a continuum between categories. A detailed quantitative analysis of the results indicated that perceivers have reliable information about the degree of category membership. Although communication forces us to partition the inputs into discrete categories for understanding, this property in no way implies that speech perception is categorical. To retrieve a toy upon request, a child might have to decide between *ball* and *doll*; however, he/she can certainly have information about the degree to which each toy was requested.

Although categorical perception has been discredited, it is often reinvented under new guises. The hypothesis of a 'perceptual magnet' is that prototypical instances of a speech category function like magnets for surrounding sounds that are less prototypical members of that category, creating sharper boundaries between categories (Kuhl, 1991, 2004). The perceptual magnet putatively creates representations which produce good discriminability of speech segments near category boundaries and poor discriminability near the category prototype. (Ideal or central member of a category or concept: Robins are prototypical birds, whereas eagles and penguins are not). Thus, the perceptual magnet effect a reformulation of categorical perception. Evidence for the perceptual magnet requires an experiment to show how discrimination is directly predicted by a measure of category goodness. Lotto et al. (1998) found, however, that discriminability was *not* poorer for vowels with high category goodness, in contrast to the predictions of the perceptual magnet theory. The same authors also observed additional negative evidence that category goodness ratings were highly context-sensitive. If category goodness is functional in discrimination, it should be relatively stable across different contexts. (Prototype Description: A summary description of a category in terms of a representation for the ideal member of the category.)

Some proponents of categorical perception are also skeptical of the view that speech is special. As evidence, they cite several experimental studies that demonstrate that nonhuman animals also produce categorical perception. The belief is that these studies reveal that spoken language capitalized on natural auditory discontinuities for defining speech categories. Perhaps the most telling negative evidence is that the 6000 or so languages of the world have carved up the speech stimulus space in very different ways, precluding this possibility (Lindau and Ladefoged, 1983). My belief is that there are too few possible discontinuities for just a single language, let alone a plethora of languages. Most importantly, the 'categorical perception' results in nonhuman animals, like the corresponding results with humans, can be equally or better explained in terms of continuous perception.

It was common to attribute categorical perception to infants as well as adults (Eimas, 1985; Gleitman and Wanner, 1982). Although early studies appeared to find that infants noticed differences only between sounds from different speech categories and not between sounds from within the same speech category, follow-up studies quickly demonstrated that infants discriminate differences within, as well as between, categories (Massaro, 1987: p. 239; McMurray and Aslin, 2005). Other infant studies revealed how rapidly infants develop an affinity for their language. Infants have been shown to behave differently to two different speech segments at 4 months of age but not at 14 months, if the two segments are not informative

in their language (Werker and Tees, 1983). This ability to quickly learn the meaningful distinctions in their language is not unique to speech. Research in sign language has revealed exactly parallel results. Infants raised with American Sign Language show a sensitivity to different handshapes at 4 months of age but do not behave differently to them at 14 months, if they are not functional (Baker et al., 2006).

More generally, research with infants reveals that they discriminate the multiple dimensions of the auditory speech signal. However, the meaning of these differences in the language must be learned, and infants are not prewired to categorize the signals into innate phonetic categories. It is just as false to attribute categorical perception to the infant and child as it is to claim that fully developed adults are categorical perceivers (Massaro, 1987).

Although categorical perception is about as old as speech research itself, we must conclude that speech is perceived continuously. Speech decisions are necessarily categorical. Research reveals conclusively that audible and visible sources of bottom-up information and top-down sources of contextual information generate continuous representations. As discussed in Section The Fuzzy Logical Model of Perception, these representations are integrated to provide a usually robust interpretation of the language input (Massaro, 1987, 1998). Most importantly, the case for the specialization of speech is weakened considerably because of the central role that the assumption of categorical perception has played (Liberman and Mattingly, 1985). Finally, several neural network theories such as single-layer perceptrons, recurrent network models, and interactive activation have been developed to predict categorical perception (Damper, 1994): its nonexistence poses great problems for these models.

Speech Perception as Pattern Recognition

The study of speech perception has matured into an interdisciplinary endeavor, which involves a varied set of experimental and theoretical approaches. It includes the fundamental psychophysical question of which properties of spoken language are perceptually meaningful and how these properties signal the message. Independent variation of several properties, along with a quantitative theoretical analysis, is a productive paradigm to pursue not only the psychophysical question but also the issue of how the multiple cues are used together for perception and understanding. We have learned that spoken language understanding is influenced by multiple sources of information from several modalities and that perceivers derive continuous information from these many sources. In addition to these bottom-up sources, higher-order context is also used in speech understanding. Several productive theoretical approaches address the complex question of how we so easily understand another's utterances.

It is commonplace to have the impression that foreign languages are spoken much more rapidly than our own, and without silent periods between the words and sentences. Our own language, however, is perceived at a normal pace (or even too slowly at times) with clear periods of silence between the words and sentences. In fact, languages are spoken at rates that can differ by about a factor of two (Pellegrino et al., 2011). The reason for these different rates appears to be due to the information density of the speech: some languages are denser than others, and it appears that all languages are spoken to have about the same density. If your language is less dense, you speak more quickly so your listener stays attentive. Even with these differences, foreign languages give the impression that they are being spoken more quickly. Our troubling experience with a foreign language is simply that we do not know it. These experienced differences with known and unknown languages are solely due to the memory structures and psychological processes involved in speech perception.

We define speech perception as the process of imposing a meaningful perceptual experience on an otherwise meaningless speech input. The empirical and theoretical investigation of speech perception has blossomed into an active interdisciplinary endeavor, including the fields of psychophysics, neurophysiology, sensory perception, psycholinguistics, linguistics, artificial intelligence, and sociolinguistics.

Given the existence of multiple sources of information in speech perception, each perceived continuously, a new type of theory is needed. The theory must describe how each of the many sources of information is evaluated, how these sources are combined or integrated, and how decisions are made. The development of a promising theory has evolved from sophisticated experimental designs and quantitative model testing to understand speech perception and pattern recognition more generally. A wide variety of results have been accurately described within the Fuzzy Logical Model of Perception (FLMP). (A logic based on the premise that propositions can be graded in truth value, rather than simply being true or false. Degree of truth is represented by a truth value between 0 (perfectly false) and 1 (perfectly true). Fuzzy logic also gives algorithms for computing the negation, conjunction, and disjunction of continuous truth values.)

The Fuzzy Logical Model of Perception

The three processes involved in perceptual recognition are illustrated in Figure 1 and include evaluation, integration, and decision. These processes make use of prototypes stored in long-term memory. The evaluation process transforms these sources of information into psychological values, which are then integrated to give an overall degree of support for each speech alternative. The decision operation maps the outputs of integration into some response alternative. The response can take the form of a discrete decision or a rating of the degree to which the alternative is likely. The assumptions central to the model are: (1) Each source of information is evaluated to determine the continuous degree to which that source specifies various alternatives; (2) the sources of information are evaluated independently of one another; (3) the sources are integrated to provide an overall continuous degree of support for each alternative; and (4) perceptual identification and interpretation follows the relative degree of support among the alternatives.

Given multiple sources of information, it is useful to have a common metric representing the degree of match of each feature. Two features that define a prototype can be related to

Figure 1 Schematic representation of the three processes involved in perceptual recognition. The three processes are shown to proceed left to right in time to illustrate their necessarily successive but overlapping processing. These processes make use of prototypes stored in long-term memory. The different sources of information are represented by upper-case letters. Auditory information is represented by A_i and visual information by V_j. The evaluation process transforms these sources of information into psychological values (indicated by lowercase letters a_i and v_j) These sources are then integrated to give an overall degree of support, s_k, for each speech alternative k. The decision operation maps the outputs of integration into some response alternative, R_k. The response can take the form of a discrete decision or a rating of the degree to which the alternative is likely.

one another more easily if they share a common currency. To serve this purpose, fuzzy-truth values (Goguen, 1969; Zadeh, 1965) are used because they provide a natural representation of the degree of match. Fuzzy-truth values lie between 0 and 1, corresponding to a proposition being completely false and completely true. The value 0.5 corresponds to a completely ambiguous situation, whereas 0.7 would be more true than false and so on. Fuzzy-truth values, therefore, not only can represent continuous rather than just categorical information, but also can represent different kinds of information. The truth values in speech perception would correspond to the likelihood of a speech category given the sensory information. The variability of the sensory information signaling a specific speech category would also influence the truth value (Bejjanki et al., 2011). (Mental Representation: The mental content of perceptions, ideas, images, beliefs, thoughts, memories, and hypotheses. These are symbols because they stand for something else. There is no reason that the representation or symbol has to be discrete).

Figure 1 also illustrates how learning is conceptualized within the model by specifying exactly how the feature values used at evaluation change with experience. Learning in the FLMP can be described by the following algorithm (Friedman et al., 1995; Kitzis et al., 1999). The initial feature value representing the support for an alternative is initially set to 0.5 (since 0.5 is neutral in fuzzy logic). A learning trial consists of a feature (such as closed lips at onset) occurring in a test item followed by informative feedback (such as the syllable /ba/). After each trial, the feature values would be updated according to the feedback, as illustrated in Figure 1. Thus, the perceiver uses the feedback to modify the prototype representations and these in turn will become better tuned to the informative characteristics of the patterns being identified. This algorithm is highly similar to many contemporary views of language acquisition (Best and McRoberts, 2003; Best et al., 2001; Werker and Logan, 1985)

In the course of our research, we have found the FLMP to be a universal principle of perceptual cognitive performance that accurately models human pattern recognition. People are influenced by multiple sources of information in a diverse set of situations. In many cases, these sources of information are ambiguous and any particular source alone does not usually specify completely the appropriate interpretation.

Multimodal Speech Perception

Speech perception has traditionally been viewed as a unimodal process, but in fact appears to be a prototypical case of multimodal perception. This is best seen in face-to-face communication. Experiments have revealed conclusively that our perception and understanding are influenced by a speaker's face and accompanying gestures, as well as the actual sound of the speech (Massaro, 1998). Although the results demonstrate that perceivers use both auditory and visible speech in perception, they do not indicate how the two sources are used together. There are many possible ways the two sources might be used. We first consider the predictions of the FLMP.

In a two-alternative task with /ba/ and /da/ alternatives, the degree of auditory support for /da/ can be represented by a_i, and the support for /ba/ by $(1 - a_i)$. Similarly, the degree of visual support for /da/ can be represented by v_j, and the support for /ba/ by $(1 - v_j)$. The probability of a response to the unimodal stimulus is simply equal to the feature value. For bimodal trials, the predicted probability of a response, $P(/\mathrm{da}/)$, is equal to.

$$P(/\mathrm{da}/) = \frac{a_i v_j}{a_i v_j + (1 - a_i)(1 - v_j)} \qquad [1]$$

In the previous work, the FLMP has been contrasted against several alternative models such as a weighted averaging model (WTAV), which is an inefficient algorithm for combining the auditory and visual sources. For bimodal trials, the predicted probability of a response, $P(/\mathrm{da}/)$ is equal to.

$$P(/\mathrm{da}/) = \frac{w_1 a_1 + w_2 v_j}{w_1 + w_2} = w a_i + (1 - w) v_j \qquad [2]$$

The WTAV predicts that two sources can never be more informative than one. In direct contrasts, the FLMP has consistently and significantly outperformed the WTAV (Massaro, 1998).

More generally, research has shown that the results are well-described by the FLMP, an optimal integration of the two sources of information (Massaro and Stork, 1998). A perceiver's recognition of an auditory-visual syllable reflects the contribution of both sound and sight. For example, if the ambiguous auditory sentence, *My bab pop me poo brive*, is paired with the visible sentence, *My gag kok me koo grive*, the perceiver is likely to hear, *My dad taught me to drive*. Two ambiguous sources of information are combined to create a meaningful interpretation (Massaro and Stork, 1998).

Recent findings show that speech reading, or the ability to obtain speech information from the face, is not compromised by oblique views, partial obstruction, or visual distance. Humans are fairly good at speech reading even if they are not

looking directly at the talker's lips. Furthermore, accuracy is not dramatically reduced when the facial image is blurred (because of poor vision, for example), when the face is viewed from above, below, or in profile, or when there is a large distance between the talker and the viewer (Massaro, 1998).

Higher-Order or Top-Down Influences

William Chandler Bagley published perhaps the first experimental study of speech perception in his dissertation in 1890. In Bagley's experiment, naturally spoken words were recorded and played back to eight members of the Cornell University Psychology Department on Edison phonograph cylinders. The words were pronounced by deleting one of the consonant sounds in the word. Bagley evaluated the effects of context on word perception: The word was presented alone, with one or two related words, and at the beginning, middle, and end of complete sentences. This experiment may have been the first systematic distortion of the spoken message, although people doubtless have been playing with the words they utter since they began uttering them (witness Pig Latin, for example). The results demonstrated that subjects were often able to correctly recognize the distorted words and, in addition, the word's context word recognition. Correct word recognition was better if the word was placed in the middle of a sentence, for example, relative to being presented alone.

Consistent with the framework being developed, there is now a substantial body of research illustrating that speech perception is influenced by a variety of contextual sources of information. Bottom-up sources correspond to those sources that have a direct mapping between the sensory input and the representational unit in question. Top-down sources or contextual information come from constraints that are not directly mapped onto the unit in question. As an example, a bottom-up source would be the stimulus presentation of a test word after the presentation of a top-down source, a sentence context. A critical question for both integration and autonomous (modularity) models is how bottom-up and top-down sources of information work together to achieve word recognition. For example, an important question is how early can contextual information be integrated with acoustic-phonetic information. A large body of research shows that several bottom-up sources are evaluated in parallel and integrated to achieve recognition (Massaro, 1987, 1994). An important question is whether top-down and bottom-up sources are processed in the same manner. A critical characteristic of autonomous models might be described as the language user's 'inability' to integrate bottom-up and top-down information. An autonomous model must necessarily predict no perceptual integration of top-down with bottom-up information.

The model tests have established that perceivers integrate top-down and bottom-up information in language processing, as described by the FLMP. This result means that sensory information and context are integrated in the same manner as several sources of bottom-up information. These results pose problems for autonomous models of language processing, which assume that perceptual outcomes are impenetrable by context effects. Evidence of multiple sources of information and perceptual influences of context effects validates our critique of categorical perception. If the auditory input constrained the perception to a single speech category, then context could have no productive influence. When the context agreed with the speech category, there would be no benefit. When context disagreed with the categorization, the perceiver would be at a loss as to what to do. Having continuous information from both bottom-up and top-down sources allows for their productive integration.

It is important to mention that the FLMP have been proven to be mathematically equivalent to Bayes theorem, which is an optimal algorithm for combining two information sources (Massaro, 1987; Massaro and Friedman, 1990). However, we prefer the common metric to be fuzzy-truth values because they more naturally represent continuous information than do the probabilities of Bayes theorem. If language processing evolved across many millennia of language use, it should not be surprising that speech communication settled on an optimal situation. The many experimental and theoretical sources of evidence for the FLMP thus in turn supports a Bayesian analysis of speech perception, which invites it within an acceptable general framework of perception and learning.

Neurological Underpinnings of Speech Perception

This article is dedicated to a psychological level of description of speech perception. Of course, there is a neurological level that can be equally informative (Massaro, 1989). Many researchers are actively involved in discovering what brain mechanisms are involved in speech perception and how they work together to allow speech understanding and to support speech production. Speech perception or recognition is distinguished from speech production in a recently proposed dual-stream model (Hickok and Poeppel, 2007). A ventral stream supports perception and a dorsal stream interfaces with articulatory networks to allow speech production. A few assumptions of the model that find support at the neurological level are relevant to our review of speech perception. First, there are brain processes that allow the influence of multiple sources of information on speech perception. Second, the model rejects outright that motor behavior intervenes in speech perception (Hickok et al., 2009). Both these assumptions at the neurological level are consistent with our conclusions at the psychological level.

Abstract

The cortical organization of speech encompasses two aspects: The decoding of the speech signal that, as for other complex sounds, begins in Heschl's gyrus and continues as a hierarchical process into anterior-lateral regions of superior temporal cortex. These nonprimary auditory areas form a ventral processing stream via the uncinate fascicle into inferior frontal cortex (ventrolateral prefrontal cortex). Neurophysiological studies in the macaque have demonstrated single-cell responses to subphonetic features like frequency sweeps and bandpassed noise bursts with specific bandwidths. Neuroimaging and direct recordings from auditory cortex confirm the existence of similar neural representations in humans. A second auditory processing stream projects from Heschl's gyrus posteriorly and dorsally through inferior parietal regions into premotor and dorsolateral prefrontal areas. This posterodorsal stream is important for the matching of articulatory features of speech with acoustic-phonetic features processed in the ventral stream.

Introduction: What is Speech?

In linguistics, speech processing is an essential part of spoken language. In the domain-general version of the word, speech is only one category of complex sounds, a category that is used to communicate with other members of the human species. The acoustic properties of this sound category are largely determined by the mechanics of the sound production machinery that humans have at their disposal. This explains why the phonetics of speech are usually described in terms of their production types and locations within the vocal tract (Ladefoged, 2001). Examples are ('bilabial,' 'velar'…), which refer to anatomical parts of the vocal apparatus, or ('fricative,' 'nasal'…), which characterize acoustic features of speech that are generated by a specific constellation of vocal tract elements. Speech sounds are also shaped by the resonance frequencies and filter properties of the vocal apparatus, thus creating 'formants.' Finally, speech throughout evolution must have been optimized in terms of transmission of information or saliency. Thus, frequency sweeps are part of virtually any human language or, for that matter, of virtually any acoustic communication system. Speech sounds obviously also have to be adapted to the human hearing range.

Processing of speech sounds occurs at every level of the auditory system. However, it is not until the level of auditory cortex that speech processing contributes to communication, and speech sounds get categorized and take on meaning. In this article, I will focus on the cortical organization of speech processing, first describing the hierarchical organization of the auditory ventral pathway, which enables the processing of speech and its constituent elements in the acoustic-phonetic domain, and second the contribution of the sensorimotor dorsal pathway in the categorization of speech sounds and matching of articulatory with acoustic-phonetic features. For the first part, we have appropriate animal models, including nonhuman primates, at our disposal that illustrate hierarchical processing of communication sounds, as examples of other complex sounds (or 'auditory objects'). The nonhuman primate model can be directly related to human imaging studies that show close parallels between these primate species. The second part on the relation between speech processing and articulation, also referred to as audio-motor coupling, is more difficult to tackle in an animal model, but I will nevertheless try.

Hierarchical Processing of Complex Sounds

The inner ear is basically built as a frequency analyzer. In a process similar to a Fourier analysis, it breaks down complex sounds into their frequency components and maps them along the basilar membrane of the cochlea (base to apex) from high to low frequencies (von Békésy, 1960). At the level of primary auditory cortex (A1), this frequency specificity is still preserved at the level of single neurons. In almost every neuron, one can find a 'characteristic' or 'best' frequency, for which the neuron shows its lowest threshold or responds with the highest firing rate, respectively. Similarly, auditory cortex maintains the neighborhood relationships between frequencies as a tonotopic map that is first established in the cochlea. At first sight, this makes primary auditory cortex appear as a cortical replication of the cochlea, just as primary visual cortex is sometimes referred to as a 'cortical retina,' because this is where perceptual processing really begins.

Indeed, auditory cortex seems to perform neural operations similar to visual cortex, which is underscored by the existence of similar cell types in both cortices: frequency modulated (FM) selective neurons have been described in A1 of cats (Mendelson and Cynader, 1985; Tian and Rauschecker, 1994) and monkeys (Tian and Rauschecker, 2004), which respond better to frequency sweeps than to constant-frequency tones, just as V1 neurons prefer moving bars over stationary spots of light (Hubel and Wiesel, 1962). Similarly, analogues of simple and complex cells have been described recently (Tian et al., 2013), which distinguish between on- and off-subregions within a neuron's response area or receptive field. This demonstrates that primary auditory cortex does in fact more than just replicate the cochlea: it begins to integrate spectrotemporal information over a small area. At the same time, these findings suggest that neocortex uses similar neural operations (a 'canonical code') across sensory modalities.

Figure 1 *Communication sounds and single neurons responding to them.* Spectrograms of conspecific vocalizations in (a) rhesus monkeys and (b) humans. Communication calls are commonly characterized by frequency-modulated (FM) sweeps and bandpassed noise (BPN) bursts. (c) Selectivity for specific vocalizations is generated by nonlinear combination of features in the spectral or temporal domain. An example of the latter is shown. A single neuron responds to the whole call, but not to its temporal components ('syllables') nor to its time-reversed version.

Cells at the next stage of auditory cortical processing, the 'belt' region situated on both sides (laterally and medially) of primary 'core' areas, integrate even more strongly across frequencies. Accordingly, belt neurons no longer respond best to pure tones but prefer bandpassed noise (BPN) bursts of a specific bandwidth and center frequency (Rauschecker et al., 1995). These frequencies are still organized in a tonotopic (or rather cochleotopic) fashion. Both BPN and FM-selective neurons are obviously suitable for playing an important role in the processing of vocalizations and human speech, as they are ubiquitous elements of communication sounds (Figure 1(a) and (b)). BPN bursts correspond to formants, and FM sweeps are analogous to formant transitions.

Parallel Processing Streams

Two of the lateral belt (LB) areas in secondary auditory cortex, the anterolateral area (AL) and the caudolateral area (CL), form the origins of two major pathways for the processing of auditory cortical information (Rauschecker and Tian, 2000). Both of these streams make an important contribution to speech processing, but in quite different ways.

Selectivity for Species-Specific Calls in the Auditory Ventral Stream

As noted earlier, neurons in the LB of the monkey generally respond more vigorously to time-variant FM sweeps than to

tones of constant frequency, and FM sweeps are also more effective than BPN bursts. When tested directly with whole monkey calls (MC; **Figure 1(a)**) or components thereof (**Figure 1(c)**), the neurons respond more vigorously to them than to pure tones. MC stimuli were also generally more effective than BPN bursts.

LB neurons responded differentially to different types of MC, especially in AL and areas anterior to it. Acoustic-phonetic response selectivity is based on specific combination, i.e., nonlinear summation, of features in the spectral and the temporal domains (**Figure 1(c)**) (Rauschecker et al., 1995). These spectral and temporal facilitation mechanisms can be compared to combination sensitivity, as described in other species (Suga et al., 1978; Margoliash and Fortune, 1992). In high-density direct cortical surface recordings in humans while they listened to natural, continuous speech, phonetic features were directly related to tuning for spectrotemporal acoustic cues, some of which were encoded in a nonlinear fashion (Mesgarani et al., 2014).

One of the most striking differences between core and belt areas identified so far is the difference in this ability to nonlinearly integrate information both in the spectral and time domain. While more than half of the neurons in LB show some form of nonlinear interaction, only ~10% (or less) of the neurons in core areas A1 or R display this form of behavior, which is one of the strongest arguments for the hierarchical organization of speech processing in auditory cortex. Areas further downstream in the auditory ventral stream show even more evidence for auditory object selectivity in neurophysiological recordings (Romanski and Goldman-Rakic, 2002; Cohen et al., 2009; Kikuchi et al., 2010, 2014).

In humans, detailed neuropsychological studies involving quantitative lesion analysis have recently confirmed that the anterior STG makes a more significant contribution to speech perception than the posterior STG (Dronkers et al., 2004). At the phonological level, phonemic discrimination between real words and nonsense syllables was little affected after lesions of posterior STG, whereas this ability was severely impaired in aphasics with lesions of anterior STG (Blumstein et al., 1977) but not in Broca aphasics, for which the anterior STG was spared. Generally, infarcts in bilateral anterior STG cause auditory agnosias, in which people fail to identify familiar sounds (Clarke et al., 2000; Vignolo, 1982), and the anterior temporal lobe is the location of atrophy in 'semantic dementia' (Mummery et al., 2000; Patterson et al., 2006). Functional neuroimaging studies also demonstrate anterior ST regions to be activated more than posterior regions when subjects listen to speech (Obleser et al., 2006; Scott et al., 2000; Binder et al., 2000) or to other complex sounds (Leaver and Rauschecker, 2010). Finally, in a meta-analysis by DeWitt and Rauschecker (2012) specific to syllables, words, and phrases, syllables were represented just lateral to Heschl's gyrus, words anterolateral to that, and short standard phrases even more anteriorly in the ST (**Figure 2**).

Figure 2 *Meta-analysis of speech sound representations in the human brain.* Results of neuroimaging studies are shown with foci meeting inclusion criteria for ALE-statistic maps for regions of significant concordance ($p < 10^{-3}$). Analyses show an anterior progression with phoneme-length studies showing greatest concordance in left mid-STG (a; $n_{exp} = 14$), word-length studies showing greatest concordance in left anterior STG (b; $n_{exp} = 16$), and phrase-length analyses showing greatest concordance in left anterior STS (c; $n_{exp} = 19$). n_{exp} denotes the number of experiments (i.e., the number of contrasts from independent samples) contributing to each analysis. Proceedings of the National Academy of Sciences of the United States of America 109 (8), E505–E514.

Spatial Selectivity and Sensorimotor Integration in the Auditory Dorsal Stream

The original dual-pathway model of auditory cortical processing (Rauschecker and Tian, 2000) assumes that two largely segregated processing streams originating in the LB subserve the two main functions of hearing: identification of sounds, including speech sounds; and localization of sounds in space. Evidence is strong, from work in both humans and nonhuman studies, that the anteroventral pathway (including anterior superior temporal cortex, aST) supports the former function (see above), whereas the posterodorsal stream (including posterior superior temporal cortex, pST, and inferior parietal lobule, IPL) supports the latter, i.e., processing of space and motion-in-space. Both findings (the assignment of speech sound recognition to aST and a role of pST and IPL in space and motion) would seem to be at odds with classical claims that assume a function in speech and language for pST and IPL in humans.

Is the Dorsal Pathway Really Involved in Speech Perception?

Many textbooks refer to pST and surrounding regions as 'Wernicke's area,' so it seems as if this view dates back to Carl Wernicke (1874), who described patients with lesions of the ST region having difficulties with various aspects of speech. Closer examination of Wernicke's case studies reveals, however,

that the pertinent lesions were not necessarily found in pST alone. A figure in one of his own textbooks (Wernicke, 1881) explicitly marked the whole ST region as speech-related, including its anterior aspects. To reserve the term 'Wernicke's area' for the posterior one-third of ST is, therefore, misleading. The role of the STG as a whole, including its anterior portions, in speech perception was all but forgotten until the linguist Harry Whitaker (1971) and the neurosurgeon Wilder Penfield (Penfield and Roberts, 1959) separately noted the shift from Wernicke's original work.

Wernicke did, however, make the insightful claim that auditory ST regions subserving the deciphering of speech sounds must be connected somehow with the motor speech area in the frontal cortex, which had been discovered by Broca (1861) about a decade earlier. Based on gross anatomical studies of aphasic stroke patients, later researchers assumed that this functional connectivity was provided by a fiber bundle that wound its way from the pST region to Broca's area, the 'arcuate fascicle' (Geschwind, 1965). Present-day work is being performed with high-resolution structural imaging techniques (Rilling et al., 2008; Bernal and Ardila, 2009; Keller et al., 2009). At least one of these studies has revealed that a direct connection from pST to Broca's area is sparse at best (Frey et al., 2008). Instead, most fibers projecting to Broca's area from ST originate in its anterior aspects and follow a ventral pathway via the extreme capsule and/or the uncinate fascicle (Ebeling and Von Cramon, 1992; Friederici et al., 2006). In fact, Wernicke himself suspected that the connection from ST to Broca's area went via the anterior insula, a region that has recently been found to play a role in communication sound processing of monkeys (Remedios et al., 2009). All this adds to the support for an anteroventral pathway in auditory speech processing and one might be tempted to reject the claim of a specific pST (and dorsal stream) involvement in speech processing altogether. However, this would be throwing the baby out with the bathwater.

In order to confirm a genuine role for the pST region in speech and language and to reconcile this role with the spatial functions of that region, one merely has to give up the claim that pST is involved in the 'perception' of speech, including the acoustic-phonetic decoding of speech sounds. Instead, one needs to analyze incidents under which pST and IPL are activated by sounds or tasks with other than spatial connotations.

Dorsal Stream: Representation of Action Sounds and Auditory Perception-Production Links in Voice and Speech

Various studies have demonstrated activation of left parietal regions while subjects were listening to sounds generated by actions, such as tool sounds (Lewis et al., 2005; Pizzamiglio et al., 2005; Engel et al., 2009). These activations often include posterior STS and STG regions, especially when contrasted with unrecognizable control sounds. One possibility is that these regions contain representations of 'doable' sounds (Rauschecker and Scott, 2009). In particular, the medial PT region has been suggested to contain templates of 'doable' articulations (not limited to speech sounds) against which incoming sounds are matched (Warren et al., 2005).

Monkey studies have shown that neurons in auditory cortex are suppressed during vocalization (Müller-Preuss and Ploog, 1981; Eliades and Wang, 2003). This finding is consistent with results from humans, which indicate that superior temporal areas are suppressed during speech production (Numminen et al., 1999; Curio et al., 2000; Houde et al., 2002). This suppression or attenuation of auditory cortex is found even with covert articulation and lipreading, suggesting the existence of an efference-copy pathway from premotor regions to auditory cortex (Kauramäki et al., 2010).

It has been argued that mechanisms of this kind may exist to help distinguish the effects of actions caused by oneself from those caused by the actions of others (Blakemore et al., 1998), specifically differentiating between one's own voice and the voices of others (Rauschecker and Scott, 2009). However, in nonhuman primate studies, auditory neurons that are suppressed during actual vocalizations are often more activated by distorted vocalizations (Eliades and Wang, 2008). This suggests a role for these neurons in the comparison of information from the auditory and motor systems during speech production (Guenther, 2006). Work in humans using distorted feedback of speech production has indeed shown enhanced bilateral activation in pST to distorted feedback, even if it is below the threshold for explicit awareness (Tourville et al., 2008).

There have also been persistent claims for a role of the IPL, i.e., the angular and supramarginal gyri, in phonology (Caplan et al., 1992), particularly an involvement in the 'phonological-articulatory loop' (Baddeley et al., 1984; Aboitiz et al., 2006). This has been confirmed in several functional imaging studies, though the precise localization of activity does vary with the type of task used (Gelfand and Bookheimer, 2003; Buchsbaum and D'esposito, 2008). What seems clear is that the IPL, like pST, is not driven by acoustic-phonetic factors in speech processing but is associated with more domain-general factors (Friederici et al., 2006; Rauschecker and Scott, 2009; Bornkessel-Schlesewsky and Schlesewsky, 2013).

Unified Function of the Dorsal Stream

As documented earlier, posterior ST regions and the IPL participate in the processing of auditory space and motion. At the same time, pST and IPL in humans are also involved in the processing and imagery of auditory sequences, including in speech and music. Both regions receive input from premotor areas in the dorsal and ventral premotor cortex (PMC). Thus, premotor areas may be responsible for assembling the motor patterns for the production of sound sequences. The sounds being produced activate neuronal assemblies in the auditory cortex, which in turn get matched with the corresponding premotor neurons that help produce the sounds. In this way, specific sensorimotor networks are established which, together, represent the sound sequences in a quasimotor code. During learning, subcortical structures like the basal ganglia and the cerebellum are active in binding the correct sets of sensory and motor neurons together.

The same process can be assumed to be at work during learning of speech and speech production. Once learned, listening to speech activates the same circuits as during

Figure 3 *Dual streams supporting speech processing in the human brain.* The anteroventral stream is shown in green and the posterodorsal stream in red. Cross-stream integration in the inferior frontal gyrus is depicted by the transition from red to green. Black dashed arrows denote feedback connections. Abbreviations: AC, auditory cortex; CS, central sulcus; IFC, inferior frontal cortex; IPL, inferior parietal lobule; PMC, premotor cortex. Numbers denote Brodmann areas. Figure is adapted from Rauschecker, J.P., Scott, S.K., 2009. Maps and streams in the auditory cortex: nonhuman primates illuminate human speech processing. Nature Neuroscience 12, 718–724.

speech production. While it may not strictly be accurate to talk about a 'motor code' for speech perception (Liberman et al., 1967), correct speech does require a closing of the loop between perception and production and will lead to activation of both networks. The connection between auditory areas in the ST and speech planning areas in the frontal cortex around 'Broca's region,' as postulated by Wernicke, runs through aST and inferior frontal cortex; the loop is closed through PMC via IPL and back to auditory cortex (**Figure 3**). Learning to produce new sounds in a foreign language should, therefore, lead to changes in both sensory and motor representations of the corresponding sounds.

This basic structure of the underlying frontoparietal-sensory loops responsible for sensorimotor planning and control is best described as that of an 'internal model' or 'emulator,' as it has been known in motor control theory and robotics (Rauschecker and Scott, 2009). Such models have been used to describe reaching movements or planning of movement trajectories (Kawato, 1999; Desmurget and Grafton, 2000; Sabes, 2000). More recently, these models have been used to model perception and imagery as well (Wolpert et al., 2003; Grush, 2004). The IPL appears to provide an ideal interface for feed-forward information from motor preparatory networks in the PFC and PMC to be matched with feedback signals from sensory areas. The goal of the internal model is to minimize the resulting error signal in this process.

The feed-forward projection from BA 44 and vPM can be considered the pathway carrying an 'efference copy' or 'corollary discharge' in the classical sense (Sperry, 1950; Von Holst and Mittelstaedt, 1950), informing the sensory system of planned motor articulations that are about to happen. This signal provides a predictive quality to activity running from frontal areas to the IPL, which therefore anticipates the sensory consequences of action. The feedback signal coming to the IPL from pST, on the other hand, can be considered an 'afference copy' (Hershberger, 1976) or reafference with relatively short latencies and high temporal precision (Jääskeläinen et al., 2004; Kauramäki et al., 2010). It can be thought of as a sparse but fast primal sketch of ongoing sensory events (Bar et al., 2006) that are compared with the predictive motor signal in the IPL in real time at every instance. In that sense, both spatial processing and real-time processing of speech (and music) make use of the same general internal model structures that enable the instantiation of smooth sequential motor behaviors, including visuospatial reaching as well as articulation of speech. At the same time, these sensorimotor loops also support the disambiguation of phonological information.

Abstract

Recent evidence has determined that numerous brain regions play a vital role in speech production. These regions include both cortical and subcortical areas, as well as white matter tracts. This article reviews research from studies in neurologic patients as well as functional neuroimaging studies with healthy individuals that delineate the neural networks underlying the planning and execution of articulatory movements.

Brain Regions Involved in Speech Production

In the nineteenth century, the French neurologist Paul Broca confirmed that speech mechanisms could be localized in the human brain. He did this by interviewing a patient with a severe speech production disorder whose output was limited to the recurring utterance, *tan*. Upon the patient's death, Broca examined the brain and concluded that the patient's inability to speak was due to a lesion in the inferior part of the frontal lobe (Broca, 1861b). A second patient also had severely reduced speech and was subsequently found to have a similar cortical lesion (Broca, 1861a).

Since the time of Broca, scientists have found that lesions to Broca's area alone are not enough to produce lasting speech deficits (e.g., Alexander et al., 1989; Dronkers et al., 2000; Mohr, 1976). Many have attempted to diagram and map additional areas that might also subserve speech and language functions. This article focuses on evidence related to brain mechanisms of speech production. Specifically, evidence will be reviewed from lesion studies, electrocortical stimulation, and functional neuroimaging, all of which are helping to elucidate the neural basis of the planning and execution of articulatory movements.

The involvement of these neural structures can best be understood in the framework of a working model that follows the utterance from its conception to its ultimate articulation. Numerous studies have confirmed that the temporal lobe is important for the translation of concepts into linguistic representations (Baldo et al., 2013; Damasio et al., 1996, 2004; DeLeon et al., 2007; Foundas et al., 1998; Raymer et al., 1997; Trebuchon-Da Fonseca et al., 2009). Once the utterance has been linguistically formulated, it must be transferred to the speech mechanisms that will carry out its production. Articulation itself requires planning, initiation, modification, and execution. In addition to Broca's area, it has become clear that many areas are involved in various aspects of speech production (Eickhoff et al., 2009; Guenther, 2006; Tourville and Guenther, 2011; Price, 2012). Each of these areas is discussed in the following sections in terms of the patient studies that have helped to identify them and the functional neuroimaging research that has corroborated these findings.

Motor Face and Premotor Cortex

The muscles of the vocal mechanism are innervated by cranial nerves V, VII, IX, X, XI, and XII, which receive impulses from the cortex via the corticobulbar tract. The motor face area of primary motor cortex, as well as premotor cortex, is believed to be the source of these projections (Duffy, 2012). Lesions to these areas result in a pure motor speech disorder with slow, effortful speech and impaired articulation but intact language (Alexander et al., 1989). Such lesions are presumed to disrupt the corticobulbar fibers that activate the cranial nerves necessary for speech.

Penfield and colleagues originally showed that a number of regions in primary motor and premotor cortex were involved in speech output, as electrocortical stimulation of these sites resulted in speech arrest (Penfield and Roberts, 1959). Similarly, Ojemann and Mateer (1979) showed that, in four cases, speech arrest followed stimulation of inferior motor and premotor regions in the left frontal cortex.

Activation of primary motor and premotor cortex is commonly reported in neuroimaging studies of speech production and is typically associated with end-point motor execution (Brown et al., 2009; Guenther, 2006; Peeva et al., 2010; Price, 2012; Riecker et al., 2005; Wildgruber et al., 1996, 2001; Wilson et al., 2004). Motor cortex activity associated with speech production, as opposed to simple movements of the articulators, is biased toward motor cortex in the left hemisphere (Terumitsu et al., 2006). There is relative consensus about the role that primary motor and premotor cortices play in end-stage speech production, but there is less agreement about the precise role and location of signals leading up to this stage, as described below.

Broca's Area

Traditionally, the literature has emphasized Broca's area as the critical brain structure for speech production. However, the function of Broca's area is continuously being re-evaluated. Data from stroke patients and from neurosurgical excision have revealed that removal or injury to Broca's area results in a transient mutism that resolves in 3–6 weeks (Dronkers et al., 2000; Penfield and Roberts, 1959). Furthermore, focal lesions to Broca's area do not result in a persisting Broca's

 http://dx.doi.org/10.1016/B978-0-08-097086-8.54018-5

aphasia, and Broca's aphasia may result from lesions outside of Broca's area (Dronkers et al., 2000). In the acute or hyperacute phase, poor perfusion and/or infarcts in Broca's area have been related to impaired speech production (Davis et al., 2008; Hillis et al., 2004); however, this association does not hold for chronic patients with Broca's aphasia (>6 months post-onset; Ochfeld et al., 2010).

With the increasing acknowledgment of the contribution of other brain areas to speech production (discussed in this article), Broca's area is currently viewed as functioning within a larger network of brain regions that support speech production (Hickok, 2012; Sörös et al., 2006). Indeed, a majority, though not all, neuroimaging studies of speech production have reported networks of activation that include Broca's area in tasks involving phonological encoding and articulation, such as picture naming, repetition, word generation, and reading (Eickhoff et al., 2009; Indefrey and Levelt, 2000; Meyer and Jancke, 2006; Moser et al., 2009; Papoutsi et al., 2009; Price et al., 2011). Fine-grained analyses have revealed distinct subregions within Broca's area that are involved in different aspects of speech production (Amunts and Zilles, 2006). For example, Papoutsi et al. (2009) compared fMRI activation in response to pseudowords made up of high versus low frequency sublexical units and found that more ventral portions of the inferior frontal gyrus were related to phonetic encoding while more dorsal regions were related to phonological encoding.

In addition, a number of non-articulatory processes have also been shown to be dependent on Broca's area (Fadiga et al., 2006). An interesting study by Emmorey et al. (2007) showed that the same portion of anterior Broca's area that was activated for overt naming with spoken production was also activated during naming with American Sign Language, suggesting that this area is *modality-independent … not strongly tied to oral-acoustic phonological features of spoken language* (p. 206).

Insular Cortex

The insula is a region of neocortex hidden beneath the intersection of the frontal, parietal, and temporal lobes. In earlier studies, the insula was implicated only vaguely in speech production (e.g., Ojemann and Whitaker, 1978; Tognola and Vignolo, 1980), but more recent studies have found a more direct association. Additional studies have shown that insular cortex is highly connected to other cortical as well as subcortical regions involved in speech production (Eickhoff et al., 2009).

Stimulation of insular cortex in patients undergoing surgery for refractory epilepsy results in speech arrest and a reduction in voice intensity (Afif et al., 2010). In stroke patients, a number of studies have linked left insular cortex to an inability to coordinate complex movements necessary for articulation. Dronkers (1996) reported that patients with apraxia of speech, a motor speech disorder, had lesions in the superior precentral gyrus of the left insula, while those without apraxia of speech did not. Dronkers concluded that this small portion of the insula is critical for coordinating articulatory movements. In a more recent set of analyses using voxel-based lesion symptom mapping, this region of the insula was most critical for complex articulatory movements when the stimuli were multisyllabic, had a high degree of travel between places of articulation, or began with a consonant cluster (Baldo et al., 2011; see also Ogar et al., 2006).

In keeping with these lesion findings, neuroimaging studies with healthy individuals have reported activation in the insula during generation of syllables and single words, word reading, and picture naming (Bohland and Guenther, 2006; Indefrey and Levelt, 2000; Kato et al., 2007; Wise et al., 1999), particularly when the tasks involve articulation of nonrepeated, novel or phonologically complex words relative to automatic or simple articulatory patterns (Moser et al., 2009; Murphy et al., 1997; Shuster, 2009; Riecker et al., 2008; but see Ackermann and Riecker, 2004; Shuster and Lemieux, 2005). An alternative hypothesis is that the anterior insula plays a role in speech production via its role in controlling breathing during speech (Ackermann and Riecker, 2010).

Superior Longitudinal and Arcuate Fasciculi

The arcuate fasciculus is a bundle of fibers that connects the temporal and frontal lobes. As it travels through the parietal lobe, it clusters with the superior longitudinal fasciculus, which incorporates frontoparietal fibers as well. The arcuate fasciculus was identified by Geschwind (1970) as the tract that could potentially connect Wernicke's language area to Broca's speech area as described in Wernicke's original model (Wernicke, 1874). The Wernicke–Geschwind model predicted that disruption of this tract would result in isolated repetition deficits. However, recently a more comprehensive production disorder has been reported. Dronkers and colleagues (Dronkers et al., 2000) found that lesions that sever the arcuate/superior longitudinal fasciculus complex result in a severe production deficit with a complete loss of propositional speech (see also Bates et al., 2003). Only automatized utterances remain. These patients have lost more than just repetition skills – they are unable to transfer any information from temporal lobe language areas to anterior speech mechanisms.

Broca's two original patients were also noted to have this same production disorder, which Broca termed 'aphemia' (Broca, 1861a,b). Dronkers et al. (2007) had the opportunity to perform MR imaging on the postmortem brains of Broca's two original patients. They found that deep lesions also existed in these brains, in addition to the lesions Broca noted in the inferior frontal lobe. These deep lesions involved the arcuate/superior longitudinal complex in both cases, suggesting that this lesion also played a role in these historic patients' production deficits.

More recent studies have confirmed a role for the arcuate/superior longitudinal complex in speech production. Using probabilistic fiber maps derived from diffusion tensor imaging of normal controls, Marchina et al. (2011) found that greater involvement of the left arcuate fasciculus predicted more profound speech production deficits. The role of the anterior portion of the left arcuate fasciculus in fluency was confirmed by Fridriksson et al. (2013) with a larger number of patients. Speech production errors have also been noted after electrostimulation of the arcuate or superior longitudinal fasciculus

during intraoperative mapping for tumor resection (Duffau et al., 2002; Maldonado et al., 2011).

Supplementary Motor Area

The supplementary motor area is located in the superior frontal gyrus and extends medially between the hemispheres. Penfield and others have shown that electrocortical stimulation of this region in patients undergoing surgical removal of epileptic tissue either causes patients to make involuntary vocalizations or interrupts their ability to speak (Penfield and Roberts, 1959).

The supplementary motor area is involved in the initiation of sequential, voluntary movements, including speech (Riecker et al., 2008; Ziegler et al., 1997). This function seems to be true for the supplementary motor area even in the right hemisphere, as demonstrated by several case studies as well as functional imaging data (e.g., Indefrey and Levelt, 2000; Laplane et al., 1977). Infarctions of the supplementary motor area often result in a transcortical motor aphasia (Rapcsak and Rubens, 1994): Spontaneous speech is initially dysfluent, but comprehension, repetition, and reading remain relatively intact. Similarly, complete excision of the supplementary motor area causes a transient aphasia with deficits in articulation that resolve quickly (Penfield and Roberts, 1959).

Functional neuroimaging tasks that elicit supplementary motor cortex activation include the control of breathing for speech and vocalization (Murphy et al., 1997) and automatic speech (e.g., reciting months of the year; Ackermann et al., 1998). Distinct portions of the supplementary motor area appear to be activated for different stages of speech production, including lexical selection, sequence encoding, and motor output (Alario et al., 2006; Riecker et al., 2008). Peeva et al. (2010) reported that a loop between the left supplementary motor area and the left basal ganglia was associated with speech production at the level of the phoneme, with specific phonemes having their own distinct representation in the supplementary motor area. One model of speech production suggests that the supplementary motor area, in conjunction with the basal ganglia, is responsible for gating the output motor signals to the articulators (Tourville and Guenther, 2011).

Basal Ganglia

The basal ganglia are subcortical nuclei comprised of the caudate, putamen, and globus pallidus that interact with motor cortex and with a number of other subcortical structures in a series of feedback loops that help to maintain motor activity (Webb and Adler, 2008). Lesions to the basal ganglia can result in several types of movement disorders including Parkinson's and Huntington's disease, which each have their own specific speech characteristics (Duffy, 2012). Patients with Parkinson's disease (which results from a lack of dopaminergic innervation of the caudate/putamen) exhibit hypokinetic speech with decreased intensity and little modulation of pitch or loudness. In contrast, patients with Huntington's disease (which results from a loss of GABAergic, inhibitory neurons in the caudate) exhibit hyperkinetic speech with erratic control of pitch and loudness. Persistent developmental stuttering has been associated with altered activity in the basal ganglia as well (Alm, 2004; Giraud et al., 2008). These data suggest a role for the basal ganglia in the modulation of articulation and phonation.

Similar disorders can be seen in patients with focal lesions in the basal ganglia. For example, Pickett et al. (1998) reported a case study of a patient with bilateral lesions in the putamen and caudate. Her speech was initially characterized as dysarthric and was very difficult to understand, with poor articulatory and phonatory control. Similarly, Fabbro and colleagues reported at least two cases in which lesions in the basal ganglia resulted in hypophonia and a reduction of speech initiation and output (Fabbro et al., 1996).

Functional neuroimaging studies have shown that regions within the basal ganglia are activated during speech production tasks, including covert speech (Nota and Honda, 2004; Riecker et al., 2005, 2008; Seghier and Price, 2010; Shuster, 2009; Wildgruber et al., 2001). Wildgruber et al. found that the basal ganglia were differentially activated depending on the rate of output and suggested that this brain region may be more critical at low frequencies. It is thought that the basal ganglia modulate motor speech output by way of inhibiting or controlling signals to motor regions (Peeva et al., 2010).

Cerebellum

The cerebellum has traditionally been thought to be involved in fine coordination of motor acts including speech. Evidence for this comes from patients with focal cerebellar lesions. Ataxic dysarthria following cerebellar injury is a motor speech disorder that appears to be due to a loss of coordination in muscular control of the speech apparatus, as opposed to loss of initiation or execution (Duffy, 2012). Mutism has also been associated with midline lesions in the cerebellum, in both children and adults (Coplin et al., 1997). However, this mutism is often transient and can resolve into ataxic dysarthric speech.

A broader theory of cerebellar function suggests that the cerebellum acts as a timing mechanism. That is, the cerebellum's role in motor coordination (for speech and other coordinated motor acts) is based on a more general mechanism that allows for the precise temporal control of such movements (Ackermann, 2008; Ivry and Keele, 1989). Consistent with this hypothesis, Gandour and Dardarananda (1984) and others have shown that cerebellar patients have abnormal voice onset time distributions. It is also argued that the cerebellum plays a role prior to production stages, as it is activated during subvocal rehearsal as well as covert production (Ackermann et al., 1998; 2007). The role of the cerebellum in speech is likely multifaceted, based on the functional heterogeneity of the cerebellum in motor control in general (Ackermann, 2008).

Conclusions

Much has been learned about the neural processes involved in speech based on studies that have examined the specific deficits associated with lesions in particular brain regions. While basic language mechanisms involved in transforming concepts

into linguistic representations cluster in posterior brain regions, speech production is generally supported by more anterior brain regions. New research has suggested a role for the insula in articulatory planning, the supplementary motor area for the initiation of sequential speech movements, the basal ganglia and the cerebellum for pitch, loudness, rate, and timing, and primary motor face cortex and premotor cortex in the execution of articulatory movements. The superior longitudinal fasciculus provides the mechanism by which language information is thought to be transferred to these anterior speech regions from posterior language areas. Functional neuroimaging studies in healthy individuals have corroborated these findings and have allowed the visualization of the networks involved in speech production online (Bohland and Guenther, 2006; Eickhoff et al., 2009; Sörös et al., 2006). Unlike early maps of the language system showing a unitary region (Broca's area) responsible for speech production, it is now clear that a large network of cortical and subcortical regions, as well as white matter pathways, work in concert at different levels of the speech output pathway (Eickhoff et al., 2009; Golfinopoulos et al., 2010; Guenther, 2006; Hickok, 2012; Kent et al., 2000). One model (Riecker et al., 2008) describes a close interaction between the left supplementary motor area, Broca's area, superior cerebellum, and insula to support the earlier stages of speech production (i.e., preparation and initiation), and a close interaction between motor cortex, the basal ganglia, and inferior cerebellum to support end-stages of speech production (i.e., execution). At the same time, much is still unknown about the precise role each of these areas plays and how they interact to support the seemingly seamless act of speech production (Tourville and Guenther, 2011). Continued progress in brain imaging methods and computational modeling will no doubt continue to provide a clearer picture in the years to come.

Abstract

Research on speech production investigates the cognitive processes involved in transforming thoughts into speech. This article starts with a discussion of the methodological issues inherent to research in speech production that illustrates how empirical approaches to speech production must differ from related fields like language comprehension. Then, an overview of the processing stages engaged in production as generally agreed upon by the different theories in the field is presented. The processing stages are: conceptual preparation – turning a thought into a verbalizable message to be expressed; grammatical encoding – developing a syntactic frame for the to-be-uttered sentence; and phonological encoding – realizing the phonological content of the syntactic frame. For each processing stage, basic theoretical assumptions, representative findings, and open issues are discussed.

Speech production refers to the cognitive processes engaged in going from mind to mouth (Bock, 1995), that is, the processes transforming a nonlinguistic conceptual structure representing a communicative intention into a linguistically well-formed utterance. Within cognitive psychology, research concerning speech production has taken various forms such as: research concerning the communicative aspect of speaking; research concerning the phonetics of the produced speech; and research concerning the details of the cognitive processing machinery that translates conceptual structures into well-formed linguistic utterances. We focus on the latter.

Native adult speakers produce on average two to three words per second. These words are retrieved from a lexicon of approximately 30 000 (productively used) words. This is no small feat: producing connected speech not only entails retrieving words from memory, but further entails combining this information into well-formed sentences. Considering the complexity of all the encoding processes involved, it is impressive that we produce speech at such a fast rate while at the same time remaining highly accurate in our production. Bock (1991) estimated that slips of the tongue occur in speech approximately every 1000 words despite the ample opportunities for errors. In the following sections the cognitive processes subserving this ability will be discussed.

Methodological Issues

The prototypical empirical approach in cognitive psychology consists of systematically varying some properties of a stimulus (input), and to measure a corresponding behavior. Systematic relations between input and behavior are then used to infer the cognitive processes mediating between them. For example, researchers interested in language comprehension may systematically vary properties of a linguistic input such as the syntactic complexity of sentences or the frequency of words, and measure a corresponding behavior, such as reading times. Differences in the latter are taken as an indication of differences in the processes engaged in building an interpretation of a sentence (the output). Thus, the input is directly observable and completely accessible to systematic manipulation, while the output and the cognitive processes leading to it are inferred from the behavior.

The situation is different for research in speech production. The input (the conceptual structure to be expressed), is not directly observable and not readily accessible for experimental manipulation. By contrast, the output (i.e., the spoken utterance), is directly observable. Given this situation, research on speech production has started by focusing on properties of the behavior. Most prominent in this respect are analysis of speech errors, and of hesitations and pauses as they occur in spontaneous speech. These analyses motivated the general theoretical framework for speech production (**Figure 1**) which is described in detail below. More recently researchers have started to make speech production accessible to standard experimental approaches from cognitive psychology (see Bock, 1996).

Figure 1 Levels of processing in speech production. Left part refers to stored representations, right part refers to processes integrating these representations into well-formed linguistic utterances.

Levels and Processes

Figure 1 provides an outline of the levels of processing involved in speech production. These levels are shared by most current psycholinguistic models (e.g., Dell, 1986; Garrett, 1988; Levelt, 1989). *Conceptual preparation* refers to the processes that transform thoughts into verbalizable messages. *Grammatical encoding* refers to the processes that turn the messages into syntactically well-formed skeletons for sentences. *Phonological encoding* refers to the processes that provide flesh to the syntactic skeletons, realizing the phonological content of the sentences. At these latter two processing levels, stored lexical information is retrieved from a long-term memory store, the mental lexicon. In particular, during grammatical encoding it is assumed that abstract lexical representations, specifying the syntactic properties of the words, but not their phonological content, are retrieved. During phonological encoding, word form information is retrieved. Finally, *articulation* refers to the processes that implement the phonetic content and turn it into motor commands for speech.

These processing levels were originally inferred from properties of speech errors (*see* Speech Errors, Psychology of). Speech errors can be analyzed with respect to the type of linguistic unit involved (words, morphemes, phonemes), and with respect to constraints that hold for errors concerning a given type of unit. For example, word exchanges (e.g., 'on the room to my door' instead of 'on the door to my room') are constrained by syntactic factors (like the syntactic category of the exchanged words) whereas phoneme exchanges (e.g., 'heft lemisphere' instead of 'left hemisphere') are constrained by phonological factors (like their position as onset, nucleus, or coda of a syllable). These and related results suggest a distinction between a processing level that is primarily concerned with syntactic processing (grammatical encoding), and another level primarily concerned with phonological processing (phonological encoding). The fact that phonemes are relevant units in speech errors also shows that the phonological form of a word is not stored and retrieved as a whole, but built from smaller units, namely the phonemes.

Planning of a sentence is not completed on one processing level and then sent to the subsequent level. For example, phonological encoding starts as soon as the syntactic structure of some part of a sentence has been determined, while the grammatical encoding of the remainder of the sentence continues. This piece-by-piece generation of a sentence is referred to as incremental production. Although there is no consensus on the size of the relevant planning units at the different processing levels, it is generally agreed upon that the size of the planning units becomes smaller as one moves from conceptual preparation through grammatical encoding to phonological encoding and articulation. Incrementality provides a natural account of fluency in speech production. Furthermore, incremental production reduces the burden of storage of intermediate results of the production process at each level.

Although there is general agreement on the levels of processing, theories differ with respect to how the flow of information between levels is characterized. According to modular views, each level of processing first produces a complete output representation for a given planning unit. Only then is this output representation passed onto the next level (e.g., Levelt, 1989). According to interactive views, every processing stage can pass partial results to the next processing level, before the output representation at the higher level has been completely specified, and lower levels of processing can provide feedback to higher levels of processing. As a consequence, processes at the phonological level can affect processes at the grammatical level (e.g., Dell, 1986). In the following sections, we discuss the different processing steps in more detail.

Conceptual Preparation

A first important goal of conceptual preparation is to establish which parts of the conceptually available information are going to be encoded, and in what order (see Levelt, 1989, for an overview). A second goal is to convert the conceptual information into a format that is a suitable for the linguistic formulation processes. One important open issue concerning conceptual preparation is how to characterize the mapping between conceptual and grammatical encoding. First is the question of whether conceptual preparation takes language specific properties into account (*see* Language and Thought: The Neo-Whorfian Hypothesis). Languages differ in which conceptual or formal properties need to be realized as a detail of the sentential form. For example, in English the word 'friend' does not carry information concerning the sex of the friend. In Spanish the corresponding word is differentially inflected for a man ('*amigo*') or a woman ('*amiga*'). In English, adjectives used as predicates (e.g., 'tall' in 'The friend of Luis is tall') do not agree in gender with the noun; in Spanish they do (e.g., '*El amigo de Luis es alto*' or '*La amiga de Luis es alta*'). Thus, in these two languages, conceptual information concerning natural gender must (Spanish) or need not (English) be conveyed by a sentence. Second is the question of whether conceptual information permeates the processes occurring during grammatical encoding beyond providing its input (Vigliocco and Franck, 1999).

Grammatical Encoding

Grammatical encoding refers to the processes involved in developing a syntactically well-formed sentence. It comprises first, those processes that map the relationships among the participants in a conceptual representation (e.g., agent, patient, etc.) onto functional syntactic relations between the words of a sentence (e.g., subject, direct object, etc.). Next, on the basis of the resulting hierarchically organized syntactic frame for the sentence, the words in the sentence are linearized in a manner allowed by the language being spoken. The first step is also referred to as *functional level processing*, the second as *positional level processing* (Garrett, 1988). Distinguishing between building hierarchical and linear frames provides a solution to an important problem that the language production system faces. Speech production has to be incremental to allow for fluent utterances, but at the same time the resulting utterance has to obey language specific constraints that force the use of only certain word orders. Assuming incremental conceptualization, however, the order in which parts of a conceptual message are processed do not necessarily correspond to a word order allowed in the speaker's language. This problem can be

solved by separating the construction of hierarchical structures from the serial ordering of the words. In this way, hierarchical structures can be built in an incremental manner as soon as lexical elements are available, these can then be mapped to permissible linearly ordered positions (Vigliocco and Nicol, 1998). Evidence compatible with such a separation comes from studies showing that the linear position of words can be primed by the previous presentation of the same linear order, even if the hierarchical structure differs (Hartsuiker et al., 1999).

An important open question with respect to grammatical encoding concerns whether the encoding at this level can be influenced by feedback from phonological encoding (Bock, 1986). Research on the process of computing number agreement between a sentence subject and a verb suggests that this grammatical process is sensitive to whether number information in the subject noun phrase is overtly realized in the phonological form of the noun, suggesting the possibility of feedback from phonological encoding to grammatical encoding (e.g., Vigliocco et al., 1995; but see Section Self-monitoring and Repair for an alternative interpretation of the results).

Phonological Encoding

Phonological encoding refers to the processes that are responsible for determining the phonological word forms and prosodic content of the sentence (e.g., Levelt, 1999). First, the phonemes of words are retrieved from the mental lexicon, together with a metrical frame which specifies stress pattern and number of syllables in the word. Following this retrieval process, the resulting sequence of phonemes is syllabified according to a language specific set of syllabification rules. The domain of syllabification is assumed to be the phonological word which can but need not coincide with a lexical word. It should be noted that in this view, the syllabic structure of an utterance is computed on-line. The reason for this assumption is that the actual syllabification of a word in running speech depends on the context in which it appears. For example, the word 'deceive' in isolation is syllabified as 'de-ceive,' but in the context of the utterance 'deceive us,' the syllable structure becomes 'de-cei-veus.' This observation also provides a functional reason why the phonological form of a word is not stored and retrieved as one entity: such a representation would have to be broken up into its constituent parts whenever the stored syllabification of a word does not agree with its syllabification in the context of running speech. The representation formed by phonological encoding, a syllabified phonological code, forms the input for the articulatory processes which realize this code as overt speech. It is an open issue whether the transition from phonological encoding to articulation involves accessing a 'syllabary,' i.e., memory representations specifying the motor tasks that have to be performed to generate each syllable (Levelt, 1999).

Lexical Access

Grammatical and phonological encoding make use of stored representations of words. Parallel to the distinction between grammatical encoding and phonological encoding, two levels of stored representation are distinguished. On one level, words are represented as abstract syntactic (and semantic) entities (technically also referred to as lemmas), and on the other level their phonological form is specified. Evidence for two levels of representation in the mental lexicon comes from tip-of-the-tongue (TOT) states. It has been demonstrated repeatedly that speakers in a TOT state can report grammatical properties of a word (e.g., the grammatical gender of a noun) above chance level even when they are unable to access the phonological form of the word.

It is unresolved whether, within the lexicon, the flow of information from meaning to form can be characterized as discrete, cascading, or fully interactive. Discrete serial models of lexical access (e.g., Levelt, 1999) assume that, first, on the basis of some fragment of a conceptual structure, a set of lemmas becomes activated. This set includes the target lemma as well as semantically related lemmas. Phonological encoding of the word is initiated only after the target lemma has been selected. Hence, the phonological forms of words which are semantically related to the target word should not become activated. Cascading models (e.g., Peterson and Savoy, 1998) assume that every activated lemma sends some activation to its corresponding word form, even before the actual target lemma has been selected. Thus, also the phonological forms of semantic competitors of the target word should receive some activation. Finally, interactive models (e.g., Dell, 1986) allow for feedback from the phonological level to the lemma level. Thus not only will the phonological forms of semantic competitors receive activation, but the phonological forms will also send activation back to all lemmas with similar phonological forms.

The question of whether the phonological forms of semantic competitors do receive activation, as predicted by cascading models and feedback models, or not, as predicted by discrete serial models, is still an empirically unresolved issue. Phonological activation of semantic competitors has been demonstrated for the case of near-synonyms like 'couch' and 'sofa' (e.g., Jescheniak and Schriefers, 1998; Peterson and Savoy, 1998) and has been interpreted in favor of cascading of activation. However, as the evidence is presently restricted to this specific semantic relation, it has been suggested that near-synonyms might be a special case (e.g., Levelt, 1999).

Concerning the question whether there is feedback from lower levels to higher levels in lexical processing, the lexical bias effect has been cited as evidence for feedback. The lexical bias effect concerns the observation that phoneme errors lead to existing words rather than nonwords more often than would be expected by chance. This finding can be explained by feedback from the level of phonological segments to some higher level representing words as one integral unit (e.g., Dell, 1986). According to discrete serial models, by contrast, the chance of incorrect selection of a phoneme should be independent of whether the resulting string of phonemes forms an existing word or not (but see Section Self-monitoring and Repair).

Self-Monitoring and Repair

Speakers not only produce speech, but also monitor their own speech output and this monitoring may occur on overt speech as well as on 'internal speech.' Assuming an internal monitor implies that not all misfunctions of the speech production system will become visible in the eventual output. Rather,

some will be discovered and repaired before they are actually articulated. Such covert repairs can play an important role in the interpretation of speech error results. For example, the lexical bias effect in phoneme errors has also been explained as the result of a pre-articulatory covert repair mechanism. This covert repair mechanism might be more likely to detect and correct phoneme errors leading to nonwords than those leading to words before the resulting error is actually produced. Hence, the lexical bias effect would not imply feedback of activation from lower to higher levels. It should be noted that related arguments have been put forward with respect to other empirical findings which appear to speak against discrete serial models, like the potential influence of phonology on grammatical encoding processes. It is a matter for future investigation to design empirical tests that allow us to differentiate between feedback and monitoring explanations of the relevant empirical phenomena.

Abstract

Speech synthesis and recognition by machines has been a fascinating topic for scientists and engineers for many years. Inspired by speaking and listening machines in science fiction, we have witnessed fast and steady technology advances in recent years. In this section, we first describe linear prediction speech analysis which is the most widely adopted model in digital speech communication and speech synthesis. Concatenative speech synthesis is then discussed for text-to-speech synthesis. It is followed by a discussion on hidden Markov modeling of fundamental speech units which is the most successful technique for both speech recognition and speech synthesis. Finally we conclude our discussion by contrasting speech recognition by humans and machines.

Speech is often regarded as the most natural means of communication among humans (Cherry 1968). The speech communication process, characterized as a *speech chain* (Denes and Pinston, 1993), consists of two parties: one speaking to the other while both listening, and vice versa. It involves human-based speech production for one party and speech recognition and understanding for the other party. Since speech is a human's unique capability, scientists and engineers have always been fascinated with the idea of replacing one of the two parties in speech communication that leads to voice user interfaces (Cohen et al., 2004). Due to advances in digital speech processing (Rabiner and Schafer, 2010) and computer technologies, the field of speech production (Fant, 1960; Flanagan, 1965) and recognition (Rabiner and Juang, 1993; Lee et al., 1996; Jelinek, 1997) by machines have made tremendous progresses resulting in a widespread deployment of speech synthesis and recognition products and services in different languages in the last two decades. We now describe the technologies behind speech production and recognition by machines in the following.

Speech Production by Machines

Mechanical devices made to produce human-like vowel sounds dated back to some acoustic resonators created by Kratzenstein in 1779 (Ohala, 2011). An illustration of a physical human speech production mechanism in a two-dimensional rendition is shown in the upper panel of **Figure 1** which displays all the human organs involved in generating the speech signal. The lungs acted as the source of excitation to pump air through trachea and vocal cords. The vocal and nasal tracts play the

Figure 1 Upper panel: A physical model of the human speech production mechanism. Lower panel: A source-filter engineering model approximating the human speech production system.

roles of resonators to shape the energy concentration in certain frequencies to create the sensation of formants, while the glottis opens and closes in a periodic manner to shape a glottal pressure wave, U_G, and create the sensation of pitch for voice sounds. Finally the sound pressure waves, U_M and U_N, are released through the lip and nostrils, respectively, into the air to produce sound waves. Different sounds are generated in sequence with different configurations in the human speech production system (Flanagan, 1965).

The whole process can be simplified in a *source-filter model* (e.g., Fant, 1960; Rabiner and Schafer, 2010) shown in the bottom panel of **Figure 1** in which the changing voice spectra are simulated by a sequence of time-varying filters with emphasis on different formant combinations. In the meantime, the source excitation, $e(t)$, is modeled by a periodic pitch-like pulse train for voiced sounds, by noise-like signals for unvoiced sounds, and by their mixtures. The speech signal, $s(t)$, is then produced by passing the excitation, $e(t)$, through the time-varying filters and concatenating the signals in time. Although the engineering approximation system is simple-minded, it is now ubiquitously deployed in all the landline and wireless telephone communication systems and implemented in all telephone handsets, smartphones, and terminal devices equipped with speech communication capabilities.

Linear Prediction Model

Linear prediction is widely considered as the most adopted model for speech waveform analysis. Following *autoregressive moving average* (ARMA) modeling of time series, such as the speech signal, short-time speech spectra can be approximated as rational spectra with a small number of poles and zeroes (Atal and Schroeter, 1978). Moreover, poles are often regarded to be keys to speech spectral representation, and therefore autoregressive (AR), or linear predictive, modeling of speech has been studied extensively in the past four decades. Almost all the modern wireless speech communication standards are based on linear predictive coding (LPC) of speech. The classic tutorial (Makhoul, 1975) and book (Markel and Gray, 1976) provide rich sources of information about linear prediction of speech. Its theory, statistical properties, and usages for distance comparison and speech recognition had also been thoroughly investigated (e.g., Itakura, 1975; Rabiner and Schafer, 2010).

In essence, given a segment of speech signal, $\{s(t), t = 1, \ldots, T\}$, each speech sample, $s(t)$, can be approximated by a linear combination of its immediately previous Q samples with a prediction error, $e(t)$, as follows:

$$s(t) = \sum_{q=1}^{Q} \mathrm{a}(q)s(t-q) + e(t)$$

where Q is the order of the *linear prediction filter* which can be used as the time-varying filters in the bottom panel in **Figure 1**, and the set of *linear prediction coefficients*, $\{a(q), q = 1, \ldots, Q\}$, can be used to form an *all-pole* spectrum for the section of speech, $\{s(t), t = 1, \ldots, T\}$, being analyzed. Furthermore, the prediction error signal, $\{e(t), t = 1, \ldots, T\}$, serves as the excitation sequence in **Figure 1**. Given the two sets, $\{a(q), q = 1, \ldots, Q\}$ and $\{e(t), t = 1, \ldots, T\}$, the signal, $\{s(t), t = 1, \ldots, T\}$, can be exactly recovered. However in practical situations, such as in today's digital speech communication, these two sets of parameters are estimated, coded, and therefore approximated, from real speech. For telephone speech, Q is usually set at 10, and the coefficient vector or its alternative representation (Markel and Gray, 1976), at each short-time instant, is vector quantized with a small number of bits to facilitate efficient encoding for wireless speech communication.

Concatenative Speech Synthesis

When we are interested in speech synthesis from text, or TTS synthesis (Taylor, 2009; Sproat, 1998), production models, such as LPC, can be adopted for speech generation. Moreover, pronunciation models associated to text have to be established after some text analysis. This is typically accomplished by segmenting real speech examples into synthesis units, such as phonemes, diphones, syllables, words, phrases, and sentences. Synthesis parameters are then extracted from these units and then concatenated according to the pronunciation specification of the corresponding texts. Finally speech is produced, segment by segment, according to the speech synthesis parameters for each corresponding unit. This process is known as *concatenative speech synthesis*. Unit extraction is a key to improve the quality of synthesized speech. Hand-labeling is often used to warrant a precise unit selection. Signal processing algorithms are also needed to smoothen the speech transition at the concatenation boundaries. Larger units, such as phrases, often produce better quality for concatenative speech synthesis than short units, such as phonemes.

Recently, hidden Markov model of units for speech recognition have been successfully adopted as speech synthesis units as well (Tokuda et al., 2013). In this case, a sequence of HMM parameters can be used to model sound transitions more smoothly than waveform concatenation, and therefore HMM-based speech synthesis often produces smooth-sounding speech which sometime implies good speech quality. As we will show later in the speech recognition section that HMM parameters can be easily estimated from a large collection of speech data with only sentence transcription, or initialized with another existing set of HMMs. It makes unit segmentation and selection not as demanding as in the conventional TTS design. It also facilitates automation of most of the TTS system production. Therefore, we have seen a fast deployment of TTS for many languages by companies, such as Google and Microsoft, because they need to offer different languages in their products and services. Similar to speech recognition design, a good TTS system for a talker often requires recording a large number of utterance examples from the particular speaker, say about 1–10 h. When personalization is concerned it is often desirable to use only a small number of talker-specific speech examples to build a TTS system. HMM-based speaker adaptation (Lee and Huo, 2000) has been adopted for parameter conversion from a set of available TTS-based HMMs to the HMMs for the target speaker. As a result, we have observed a reasonable speech quality with only few minutes of speech examples from the intended speaker. However, the synthesized speech does not sound entirely similar to the intended target speaker. More research is needed.

Speech Recognition by Machines

In science fictions, we have often seen machines equipped with an amazing ability of performing human-centric tasks. For instance, *HAL9000*, in Arthur Clark's '2001: A Space Odyssey' is fluent in speech communication, singing, playing chess, and lip reading. Even after 30 years of fast technology progresses since HAL's conception, only some of these capabilities demonstrated by HAL can be realized in today's world as indicated in the commemorative book *HAL's Legacy* (Stork, 1997). Knowing the difficulty in automatic speech recognition and understanding (ASRU) by machines, and inspired by the unlimited possibilities offered by *intelligent* voice communicators, scientists and engineers have been working hard on this topic in the last 50 years. All the effort can be summarized in two focused tasks, namely, speech-based problem solving demonstrated by R2D2 and speech translation demonstrated by *C–3PO*, in George Lucas' space saga films *Star Wars*.

The first realization of ASR was a hardware for spoken digit recognition of a single person with telephone-quality speech (Davis et al., 1952). Speech analysis and pattern matching were performed by analog circuits. By examining the knowledge sources used by humans in speech understanding as shown in the upper panel in **Figure 2**, starting from the left-hand side, we see that knowledge in acoustic phonetics (Stevens, 2000; Olive et al., 1993) is used for acoustic models to recognize sound patterns, then in phonotactics to build lexical models to recognize feasible sound sequences, and subsequently in syntactics to form language models to recognize word sequences. These three pieces are the fundamental building blocks to establish an *automatic speech recognition* (ASR) system. The reader is referred to the textbook (Rabiner and Juang, 1993) for a comprehensive introduction of the ASR theory.

By adding a semantic model to the ASR module we can perform *spoken language understanding* (SLU). Finally by incorporating discourse and dialogue history into a pragmatic model, we can have *dialogue management* (DM), an essential component for speech-based problem solving. If we replace the DM module by a machine translation (MT) module, we can establish a speech translation system. Moreover, if a spoken response component is needed, then text responses in DM and MT can be converted into speech of the listener's language through TTS synthesis (e.g., Taylor, 2009; Sproat, 1998) as we have discussed earlier. We will now examine the ASR system implementation in detail in the following.

Shannon's Channel Decoding Paradigm

Assume that a talker formulates a sequence of words, W, to speak out and utter a speech signal, $\{s(t)\}$. This process can be considered as converting W into $\{s(t)\}$ through an unknown *channel*. Therefore an inversion process to infer W from $\{s(t)\}$ can then be formulated as a channel decoding problem (Shannon, 1948). Suppose the speech signal can be represented as a sequence of feature vectors, X, and the joint distribution of X and W is denoted as $P(X, W)$. Then we can simplify the problem by assuming the input to the channel is X. Condition on X, then the channel can be characterized by the distribution, $P(W|X)$. Now ASR can be formulated as a channel decoding problem to maximize the posterior probability, $P(W|X)$. By using *Bayes rule*, we have $P(W|X) = P(X|W)P(W)/P(X) = P(X, W)/P(X)$. Since $P(X)$ is the same for all

Figure 2 Upper panel: Knowledge sources used for automatic speech understanding (ASU). Lower panel: Block diagram of a state-of-the-art automatic speech recognition (ASR) system.

sentences W, in the search space Γ, and can be dropped, the optimization problem is equivalent to maximizing the joint probability, $P(X, W) = P(X|W)P(W)$, that is,

$$\widehat{W} = \text{argmax}_{W \in \Gamma} P(X|W)P(W)$$

where the optimal word sequence $\widehat{W}$ is obtained by searching all possible sentences in Γ. This is the well-known *minimum risk Bayes decision rule* (e.g., Jelinek, 1997) which achieves the smallest number of sentence errors when the distributions, $P(X|W)$ and $P(W)$, are given to the ASR system designers.

In the real world the two key distributions are not exactly known and their forms need to be assumed and their corresponding parameters need to be estimated from a large collection of speech and text examples, commonly known as *training data*. The estimated distributions can then be used to replace the unknown distributions in the above equation and it becomes the *plug-in maximum a posteriori* (PIMAP) decision rule (Lee and Huo, 2000) which is commonly adopted in all state-of-the-art ASR systems. Although the optimality of the minimum risk Bayes decision rule can no longer be preserved as the distributions for the acoustic and languages are not known, a good speech recognition performance has been observed in many practical ASR tasks.

Speech Recognition System Design

A block diagram of a typical speech recognition system is illustrated in the bottom panel of **Figure 2**, in which the feature extraction module on the left-hand side of the system converts the input signal into a sequence of feature vectors, X, which is then decoded by two modules, acoustic and language matchers, to come up with a recognized sentence. As in LPC-based speech analysis, discussed earlier, short-time Fourier transform (Rabiner and Schafer, 2010) is usually performed at every 10 ms with a 30-ms window to obtain the speech spectrum and then converted into short-time cepstrum (Rabiner and Schafer, 2010). The feature vector at every time instance, $x(t)$, is then formed by concatenating a 13-dimension cepstral vector with its first and second time derivatives to obtain a 39-dimension vector. The quantity X is simply represented by $\{x(t), t = 1, \ldots, T\}$, where T is the number of 10-ms frames in the speech utterance $\{s(t)\}$.

The two quantities needed to evaluate the product in the right-hand side of the above equation, $P(X|W)$ and $P(W)$, are obtained as follows: the acoustic matcher uses phoneme and word models to compute conditional acoustic probability, $P(X|W)$, for a given word sequence W, which can be represented by a sequence of phoneme sounds because each word w in W can also be characterized as a sequence of phonemes according to a word pronunciation dictionary. Furthermore, the language matcher uses task language models to compute word sequence probability, $P(W)$, which can be evaluated with word n-gram probabilities, trained from a large text corpus (Manning and Schutze, 1999). On the other hand the acoustic probability is usually evaluated with hidden Markov model (HMM) (Rabiner, 1989) of phonemes. We will describe this model in detail in the next subsection.

Both models not only give good ASR performances but also fit into the framework of *finite state network* (FSN) representations of *knowledge sources* so that the speech recognition problem can be solved as a *network search* problem over a complex network representation of speech and language with each node in the network characterized by spectral variation of different sounds while each directed arc in the network representing permissible transitions between sounds following both phonotactic and syntactic models imposed by lexical and grammatical constraints shown in **Figure 2**. For a 20 000-word *large vocabulary continuous speech recognition* (LVCSR) task with each word on an average composed of 5 phonemes and 3 states per phoneme HMM, the FSN will have about 300 000 nodes and a few billion arcs for a trigram grammar. Moreover, the network search needs to be carried out at every 10-ms frame and this poses a tremendous computational challenge. *Dynamic programming* (DP) algorithms and *beam search* techniques have been adopted (Ney and Ortmanns, 2000) to efficiently search this type of huge networks in real time using modern hardwares.

Hidden Markov Model

To this date, the most widely adopted modeling approach to ASR is to use a set of HMMs as the acoustic models of subword (e.g., phonemes or syllables) or whole-word units to approximate $P(X|W)$, and to use the statistical n-gram model as language models for words to approximate $P(W)$ (Rabiner, 1989). By using the plug-in MAP decision rule discussed earlier, it has been shown that given a large set of *representative* training speech and text data, good statistical models of speech and language can be constructed to achieve a high performance for a wide range of ASR tasks. Therefore, HMMs and n-grams seem to provide a good approximate parametric forms for $P(X|W)$ and $P(W)$, respectively. Although speech is not generated by HMMs, they are mathematically well-defined and capable of simultaneously modeling both the spectral and temporal variation in speech. The HMM and n-gram parameters are usually estimated with the *maximum likelihood* (ML) criterion (Rabiner, 1989; Jelinek, 1997). The first implementation of an HMM-based ASR system was demonstrated in the Dragon System (Baker, 1975). Progress in acoustic modeling with HMM has advanced a great deal in the last four decades (Lee and Huo, 2000).

The probability distribution function characterizing each HMM state can be as simple as a Gaussian density or as complicated as a Gaussian mixture model (GMM) (Rabiner and Juang, 1993) to model spectral variation of different sounds. It can also be approximated by a neural network (Bourlard and Morgan, 1994). More recently deep neural network (DNN), with multiple and wide hidden layers, has been revitalized to model HMM state observation densities and even for feature extraction due to a discovery of efficient learning architectures and algorithms (Hinton and Salakhutdinov, 2006). It has been shown to improve accuracies for many standardized ASR tasks and other applications.

Human versus Machine Speech Recognition

Following the ASR system design methodology discussed earlier, the state-of-the-art ASR systems often achieve a high recognition accuracy for well-formed utterances for resource-rich tasks in which a large collection of speech and text

examples is available for training. However, the ASR problem is still far from being solved because not all information available in the speech knowledge hierarchy can be easily integrated into the FSN representation of the task used for decoding. When compared with human speech recognition (HSR), ASR systems often deliver much more recognition errors on the same task, especially in adverse conditions (Lippmann, 1997).

It is believed that some of the current issues of integrating various knowledge sources in top-down integrated search (Ney and Ortmanns, 2000) can be partially addressed by processing techniques that can take advantage of the full set of acoustic and language information in speech. It has long been postulated that HSR determines the linguistic identity of a sound based on detected evidences or cues shown in the top panel of **Figure 2**. This calls for a bottom-up framework that links speech processing with information extraction, by spotting speech cues with a bank of attribute detectors, weighing and combining evidences to form cognitive hypotheses, and verifying these theories until a consistent recognition decision can be made. The recently proposed automatic speech attribute transcription (ASAT) (Lee and Siniscalchi, 2013) framework is an attempt to mimic some HSR capabilities with asynchronous speech event detection followed by bottom-up knowledge integration and verification. In the last few years it has demonstrated good potentials; again, more research is needed.

Abstract

In many alphabetic orthographies a written word encodes phonemes, morphemes, and several types of constraints. This paper reviews whether children are sensitive to these different types of encoded information and at what age. The results of experiments are related to so-called stage models, which claim that children progress through a series of well-delineated stages, each of which is characterized by the mastery of a new skill. Many experimental data are incompatible with stage models. Some important findings on the spelling performance of experienced spellers are reported. The paper ends with the question whether spellers rely on abstract rule representations or not.

The Rise of Current-Day Psycholinguistics

Although the study of language with the techniques of experimental psychology is certainly much older than many researchers think (see Levelt, 2012), the way in which the mental processes and representations that subserve language use are currently studied does not date back very far in time. As a matter of fact, current-day psycholinguistics is largely the result of the cognitive revolution that was initiated by the linguistic work of Noam Chomsky in the early sixties (Chomsky, 1965). One of his main ideas – that language could be considered a mental organ whose internal structure could be studied on the basis of systematic observation – paved the way for researchers who were interested in the nature of that 'mental organ': its design (structure) and the processes operating on that structure.

However, there is a considerable difference between the goals that Chomsky set himself and the goals of current-day psycholinguists. Chomsky's main goal was to identify the mental foundations behind language (essentially syntactic foundations). His method was to identify which sentences are well-formed (syntactically possible) and which ones are ill-formed in a language. In doing so he hoped to find universal constraints on any language, a set of syntactic restrictions that is innate, specific to the human species, and, hence, genetically encoded. It was a major departure from the prevailing behaviorist doctrine, whose proponents refused to speculate on mental structures and processes because such 'entities,' by definition, escape direct observation; and for that reason (according to behaviorist belief) do not lend themselves to scientific study. (Note that behaviorists never denied the existence of mental processes and representations; they only claimed that it is impossible to study them in a scientific way. Note also that Chomsky was never interested in mental processes but only in the basic syntactic design (the overall mental structural framework) of human languages.)

As the result of Chomsky's focus on the mental underpinnings of language – even though he was never interested in the mental processes and actual representations that are mobilized in actual language use, like speaking (which he referred to as performance, in which all sorts of processes distort a clear view of the hard-wired core of the innate language faculty) – he stood at the beginning of a new scientific era. In this era, psycholinguists, i.e., experimental psychologists with an interest in language or linguists with an interest in the techniques from experimental psychology, started to wonder how it is possible to engage so fluently and automatically in language activities like speaking, listening, reading, and writing. From the end of the sixties of the previous century, psycholinguists designed experiments in which they attempted to unravel the mental processes and representations that are involved in these highly automatized language activities. It follows that these researchers were interested in performance. As a matter of fact, language performance constituted their object of study.

The current contribution deals with the psychological processes and structures that are involved in spelling. As a matter of fact, many psycholinguists are not concerned with spelling. The bulk of experimental work in psycholinguistics deals with the processes that are involved in speech processing (production and perception) and in visual word recognition (reading). This is understandable: all these activities instantiate forms of overtrained behavior: the processes operating over the mental representations that are needed to perform these activities have become automatic and are executed so rapidly, that they even escape our ability to achieve conscious control over them. For instance, we have to make no effort to understand a person who speaks our language, nor can we fixate on a written word and refuse to recognize it. The latter fact is nicely demonstrated by the Stroop effect: people have a hard time saying that the word 'blue' is printed in yellow, for instance, due to a conflict between the recognition of the color and the automatic and fast recognition of the word, which cannot be brought under conscious control (Stroop, 1935). The automaticity that characterizes these language activities is the result of the fact that most people continually engage in these forms of language behavior, i.e., every single day of their lives. The issue that fascinates psycholinguists so much and drives their research questions is, which mental processes make it possible to speak, listen, and read so effortlessly, i.e., why these processes have become automatic and how this automaticity should be understood.

In contrast to these highly automatized language activities, writing is a great deal less automatic. It requires much more conscious attention and involves many more active decision processes than the other three forms of language use. Accordingly, it falls somewhat out of the central focus of

 http://dx.doi.org/10.1016/B978-0-08-097086-8.53039-6

psycholinguists' work. Spelling, being the most peripheral component of the writing process (leading to the actual output of the word in the form of a sequence of letters), also often requires conscious deliberation about how to spell a word, especially when complex spelling rules are involved. Despite this, spelling is the most automatized aspect of the writing process. Moreover, even though spelling is a less automatized form of language activity than speaking, listening, and reading, it still deserves to be studied in its own right because (like the other forms of language activity) it requires complex mental processes and representations. Psycholinguists studying the spelling process are interested in the factors that affect these processes and representations.

What Does a Written Word Encode?

In what follows I will focus exclusively on insights that have been gained from the study of alphabetic writing systems. Space limitations make it impossible to cover the entire spectrum, including research on logographic and syllabic writing systems.

An alphabet is a system of written symbols (letters) that are used to represent the phonemes in the spoken language. Because many languages have more phonemes than the available number of letters in the alphabet they often take recourse to letter combinations to represent some phonemes (e.g., the 'ea' in 'head,' the 'ou' in 'cough'). Hence, phonemes constitute the first piece of information that is encoded in written words.

Even though alphabetic writing systems involve mappings between phonemes and graphemes, some of these systems are more complex than others. The so-called shallow alphabetic systems (e.g., Italian, Czech) come close to one-to-one mappings between phonemes and graphemes, i.e., any given phoneme is almost consistently represented by the same grapheme. At the other end of the continuum, we find the so-called deep alphabetic systems, which involve much more complex mappings between phonemes and graphemes, i.e., a single phoneme can be represented by different graphemes, depending on the word in which it occurs (e.g., the English phoneme 'i' can be represented by 'ee' as in 'tree'; 'ea' as in 'tea'; 'e' as in 'me'; 'y' as in 'theory').

However, many alphabetic writing systems do not only encode phonemes. Often they also orthographically represent morphemes. In such orthographies, the spelling pattern of a morpheme is kept constant across the set of words in which it occurs. In such cases, the orthographic pattern does not match the pattern that would be obtained by applying phoneme-to-grapheme mappings. Whenever the application of the phonological and morphological spelling principles predicts two different spelling patterns, the morphological principle overrides the phonological one.

There are two situations in which this occurs (see also Pacton and Deacon, 2008). The first situation is when the pronunciation and/or the stress pattern of the same morpheme may differ across morphologically related words. Examples are 'heal'-'health' and 'nation'-'nationality.' As can be seen, the spelling of the derived word does not represent its pronunciation (otherwise the spelling of 'health' would be 'helth') but its morphological structure. In English (and the orthographies of many languages), this morphological spelling principle also applies at the level of the suffix. For instance, the past tense suffix in the verb forms 'kicked,' 'called,' and 'committed' is always spelled as 'ed,' even though the suffix is pronounced as 't,' 'd,' and 'Id' respectively. Clearly, the variation in the suffix pronunciation is not orthographically represented and priority is given to the principle of keeping the spelling of the suffix constant.

The second situation is when application of the morphological principle results in the spelling of letters that cannot be heard in the pronunciation of the word, the so-called 'silent' letters. The French language contains lots of words containing such letters. The final letter in 'galop' ('gallop') and 'prend' ('take') is not pronounced but is yet spelled, because the sound corresponding to this letter ('p' and 'd' respectively) can be heard in the morphologically related French words 'galloper' ('to gallop') and 'prendre' ('to take'). A similar phenomenon can be observed in Dutch, where the third person singular, present tense always ends in the letter 't' (representing the 't' suffix), even when this suffix cannot be heard in the pronunciation of the verb form. Hence, the third person singular, present tense of the verb 'worden' is 'wordt' (stem + t,) even though the 't' cannot be heard, due to the fact that a stem-final 'd' is already pronounced as 't.' Hence, 'word' (stem and first person, singular, present tense) and 'wordt' are homophones. However, despite the fact that the 't' is a silent letter in 'wordt,' it is spelled because it can be heard in other third person singular, present tense forms like 'wast' ((wast), 'washes'). Note that the motivation for spelling the silent letters in the French examples above is due to derivational relationships between words, whereas it is due to an analogy between grammatically equivalent forms in the case of the Dutch examples (all of them being third person singular, present tenses). However, the overarching principle is the same: application of the morphological principle ('one morpheme, one spelling pattern').

Besides phonemes and morphemes, orthographies also use graphemes to reflect contextual constraints. Three types of such constraints can be distinguished: positional, graphemic, and phonemic ones. The spelling of the English phoneme 'k' is an example of a positional constraint on spelling. This phoneme can be spelled as 'ck' in word-final position but never in word-initial position: compare 'car,' 'kill' to 'truck,' 'clock.' The spelling of the English phoneme 's' is an example of a phonemic constraint: it is generally spelled as 'se' when following the vowel 'au' but as 'ce' when following the vowel 'ai': compare 'house,' 'mouse' to 'rice,' 'mice.' The phoneme 'z' illustrates what is meant by a graphemic constraint. In word-final position this phoneme is always spelled as 's' when preceded by a consonant but can be spelled in several ways when preceded by a vowel: compare 'dreams,' 'falls,' 'bears' to 'bees,' 'buzz,' 'please.' As these constraints are encoded in written words, spellers may become sensitive to them, even though in some cases the constraints only reflect tendencies and no absolute rules.

Now that we know the different types of information that are encoded in written words, we will see to what extent they have an impact on the spelling process. We will largely concentrate on what has been discovered about the spelling processes

of children, but will also devote a section to factors that affect the spelling process of experienced writers.

Which Factors Affect Children's Spelling?

First, a short description will be given of what has been considered the prototypical model of spelling development in children: the stage model. Then evidence will be presented on children's sensitivity to the different types of information that are encoded in written words. This evidence will be useful to assess the validity of stage models as a description of how children learn to spell.

Stage Models Spelling (and Reading)

Stage models (Ehri, 1986; Frith, 1980; Gentry, 1982) are models about children's progression as they learn to read and spell. Children's knowledge in a particular stage about written words is both applied for reading and spelling purposes. The most salient property of stage models is that they set out from the assumption that the child learns to master the spelling of words by progressing in a stepwise fashion, through a number of stages, which are clearly delineated from each other. Each stage is characterized by the child's sensitivity to a particular kind of information. For instance, skills that are mastered in the second stage are not available to the child in the first stage yet.

Let us take Frith's stage model as an example in case. In the first, so-called logographic phase the child focuses on salient letters in a word. At this stage it has access to only a small number of words (sight vocabulary). It can read these words and also makes attempts to spell them by relying on a number of salient features. For instance, the fact that the word 'yellow' has two sticks in the middle distinguishes this word from other words and is a property that assists the child in reading and spelling this word. However, a reading and spelling strategy based on this type of salient feature in written words cannot be successful in an alphabetic spelling system, for the simple reason that these features quickly lose their distinctiveness when more words are learnt. When a word like 'follow' or 'hollow' is learnt, the two sticks in the middle of the word are not helpful any more. The failure resulting from a reliance on salient properties in written words makes the child move into the alphabetic phase. In this phase the child learns that letters represent sounds, i.e., it achieves insight into the basic property of an alphabetic script: that in order to read or spell, one has to connect letters or letter combinations (graphemes) to sounds (phonemes) or vice versa. However, the application of grapheme-to-phoneme (GP) conversions or phoneme-to-grapheme (PG) conversions does not guarantee that a word is correctly read or spelled. For instance, applying these rules to read or spell a word like 'health' will fail: the vowel will be read as the 'ea' in 'heal' and the word will likely be spelled as 'helth.' In order to become a fluent reader and speller in the language the child, therefore, has to move on to the final phase: the orthographic phase. In this last phase it overcomes the shortcomings of mechanically applying GP and PG conversions and learns the conventional spellings of words.

This sounds like a neat story. It seems intuitively plausible that children acquire literacy in such a stepwise fashion. However, is this indeed the way they learn to spell? We will attempt to answer this question by reporting evidence pertaining to the kinds of information children use when spelling and the ages at which they can use this information. To anticipate the outcome of this exercise: the evidence does not confirm the idealized concept of stage models but rather overwhelmingly suggests that children are sensitive to different types of information at the same time. We will structure our analysis in terms of the three information types discussed in the section 'What Does a Written Word Encode?'

Children's Sensitivity to Phonological Information

Frith's second stage – the alphabetic stage – marks the onset of 'true' spelling. When children realize that letters are the same 'things' as sounds but in the visual modality, i.e., that they represent sounds, they have discovered the essence of an alphabetic script. Hence, it is reasonable to expect that when a child learns which letter represents which sound, it will be able to spell many words, including words that it has never seen before. A simple prediction follows: children who are quick in discovering this key of alphabetic scripts will become the best spellers (and readers).

Note that it can be anticipated that children who have to learn the relationships between phonemes and graphemes in a deep orthography, where the same grapheme can represent different phonemes or a single phoneme can be spelled in different ways, will have a harder time learning to spell (and read) than their peers in shallow orthographies. Any system based on one-to-many mappings is obviously more difficult to master than a system based on one-to-one mappings.

English-speaking children, indeed, experience more problems in learning GP and PG mappings. As an (important) aside, this has caused one of the biggest problems in the history of reading education in the United States: the adoption of the look-and-say method (also known as the whole-word method). This method explicitly bypasses GP mappings because many graphemes correspond to different phonemes, inevitably causing many errors in reading. To avoid these problems the method states that children should be trained in recognizing whole words, i.e., unanalyzed letter patterns, which they directly have to connect to their pronunciation. The results of using this method have been dramatic: many American children failed to learn to read and spell successfully. In an influential book with the significant title 'Why Johnny Can't Read – And What You Can Do About It' (Flesch, 1955), the author offers a simple explanation for the question that is implicit in the title: children who are dependent on the look-and-say method are denied the benefit of GP and PG mappings, which form the backbone of any alphabetic script. Note that even in a deep orthography as the English one, many letters are always sounded out in the same way, especially consonants (e.g., 'b,' 'd,' 'f,' 'k,' 'm,' 'p,' 's,' 't,' 'v,' …). A quarter of a century later the same author re-emphasized his message in a book whose title cannot be misinterpreted: 'Why Johnny Still Can't Read – A New Look at the Scandal of our Schools' (Flesch, 1981). The answer was again very simple: because educational programs still eschewed a phonics

approach and favored the look-and-say method – the latter being the ideal ingredient for creating bad readers (and spellers).

Flesch's emphasis on the importance of a phonics approach to teaching reading (and spelling), based on the observation that look-and-say programs dismally fail, suggests that a sensitivity to phonemes is an indispensable part of learning to become literate. This has, indeed, been confirmed in many experiments. For instance, the longitudinal research reported by Caravolas et al. (2001) showed that phoneme awareness and knowledge of letter–sound correspondences predicted English children's spelling success in the first year of formal schooling. Children with high scores produced the most phonologically acceptable (not necessarily correct) spellings. Importantly, other cognitive measures such as IQ and memory did not explain significant variance between children's performances. An additional finding was that the best spellers in the first year also performed best in producing the conventionally correct spellings in the second year, which sometimes deviated from the spellings yielded by applying PG conversions. This finding suggests that phonological awareness is a strong initial driving force when learning to spell, and that once the insight has dawned upon the child that graphemes represent phonemes, the way has been paved for a successful trajectory in learning to spell. Note that this research was done in English, a language with a deep orthography. Hence, even in such a language, phonological awareness and a good knowledge of PG mappings are crucial in learning to spell.

In this respect, the study by Caravolas et al. (2005a) is interesting. The results showed that phoneme awareness had the same impact on spelling performance in Czech, which has a highly consistent orthography, as in English, with its inconsistent orthography. In other words, mastery of PG mappings is crucial in learning to spell, irrespective of their consistency: "Phoneme awareness appears to be a core component skill of alphabetic literacy, which is equally important for learners of consistent and inconsistent orthographies" (p. 107). Flesch would be delighted with this outcome.

Obviously, a child's learning speed will be higher when the orthography has highly consistent PG mappings, i.e., children will make more errors in deep than in shallow orthographies, even when they are aware of the phonemes in the speech stream and of the PG mappings. However, this difference in learning to spell correctly does not discredit the most important issue: phonological awareness – the possibility to recognize phonemes in the seamless sound-stream and, hence, the ability to relate these phoneme units to orthographic units – is the engine of learning to spell in any alphabetic system. (For additional evidence, see Caravolas et al., 2005b; Cunningham, 2006.)

One might hypothesize that phonological decoding is a first step (the engine) in helping a child to become literate but that with increased experience, reliance on PG mappings diminishes. Although this idea does not sound unreasonable at first sight, it does not fit the facts. In a large regression study of French children from first through fifth grade, Lété et al. (2008) discovered that feed-forward consistency, i.e., the consistency with which phonemes are mapped onto graphemes, was a strong predictor of spelling performance in all grades and, moreover, did not vary across grades. Hence, phonological awareness and the associated use of PG mappings are not only crucial but also constant factors in spelling.

The assertion of stage models that at a particular time in their literacy development, children need to become consciously aware of phonemes in order to be able to map them onto the units of an alphabetic script (graphemes) matches the facts. Children who quickly learn GP and PG mappings become good readers and spellers. The ones lagging behind in this learning process become poor readers and spellers. The question is whether children can become aware of several units of information (see Section What Does a Written Word Encode?) at the same time. We will take up this question in the following sections.

Children's Sensitivity to Morphological Information

Is there any evidence in children's spellings that they are aware of the morphological structure of a spoken word – and that they take this awareness into account when spelling that word? The answer emanating from several experiments is: yes. The first evidence supporting this answer comes from the work reported by Rebecca Treiman and her colleagues. Treiman et al. (1994) studied five- to eight-year-old children and compared their spelling performance on words like 'duty' and 'dirty,' i.e., words in which the 't' is realized as a 'd' in American English. As the 'r' is inaudible, the pronunciation of the two words only differs in the vowels. Still, children made significantly more errors of the type 'dudy' than of the type 'didy.' The authors explain this finding by appealing to children's early sensitivity to morphemes (morphological awareness): they more often write the 't' in a form like 'dirty' rather than in a form like 'duty' because they are somehow aware that the former word is derived from the root 'dirt,' whereas such a derivational relationship is not present in the case of words like 'duty.' Treiman and Cassar (1996) arrived at a similar conclusion when comparing words like 'brand' and 'canned.' In both cases the spoken version of these words ends in the consonant cluster 'nd.' Young children have the tendency to leave out the first letter in consonant clusters, i.e., consonant clusters are difficult and for that reason often simplified. However, the number of such omission errors was much larger for monomorphemic words like 'brand' than for multimorphemic words like 'canned.' Again the authors suggest that this finding indicates that children are sensitive to the fact that 'brand' is not derived from another word whereas 'canned' is. They will leave out the 'n' in 'canned' less often because they realize that it belongs to the stem of the word: 'can' (i.e., they have morphological awareness).

Importantly, Deacon and Bryant (2006) countered the possible critique that superior performance on multimorphemic words might result from the fact that the embedded morphemes have a higher frequency of occurrence than the letter groups in monomorphemic words, such that the so-called morphological effect would, in fact, be an orthographic effect in disguise. They controlled for orthographic frequency by comparing children's spelling performance on orthographically matched words that only differed in their morphemic status: monomorphemic versus multimorphemic (inflected words). Example pairs are 'rocket'–'rocked,' 'turnip'–'turning.'

The spelling of the first segment ('rock,' 'turn') corresponding to the stem in the inflected words was better in the multimorphemic words. This finding indicates that the effect is a true effect of morphological sensitivity rather than the reflection of orthographic frequency.

These findings are not limited to English. In French, too, researchers have shown early effects of morphological awareness in the spelling of words. As mentioned earlier one salient characteristic of French is the omnipresence of silent letters, i.e., letters that are not pronounced in word-final position (e.g., 'tabac,' 'tabacco,' where the final consonant letter is not pronounced). Sénéchal (2000) and Sénéchal et al. (2006) showed that children who are good spellers use morphological strategies to determine whether a letter that is inaudible should be spelled nonetheless. For instance, when having to spell the noun 'galop' ('gallop'), whose 'p' is not pronounced, they relate it to the verb 'galopper' ('to galop'), where a 'p' sound is heard, and thus infer that a 'p' should also be spelled in the noun 'galop,' even though it cannot be heard in the word's pronunciation. The ability to spell these morphologically motivated, silent letters was predicted by a task that tapped into the children's morphological awareness: a morphologically based analogy task. Children were presented with a word pair like 'gris'–'grise,' which are respectively the masculine and feminine forms of the French adjective for 'gray,' and were asked to provide the second word for probes like 'blond' (answer: 'blonde'). Children obtaining high scores on this analogy task also obtained high scores on the spelling of words containing silent letters, indicating that good morphological awareness is a predictor of the ability to correctly spell morphologically motivated, silent letters. Casalis et al. (in press) showed that such a morphological spelling strategy sometimes results in overgeneralization errors: using the verb 'numéroter' ('assign a number') as a reference word, children will sometimes spell 'numérot' ('number'), based on the erroneous inference that an audible 't' in the verb reveals a silent letter 't' in the noun (the correct spelling is 'numéro').

The early development of morphological awareness and the fact that even very young children already make use of that awareness for the purpose of spelling words is bad news for stage models. This finding is incompatible with the assumption of distinct stages that succeed each other in a neat, developmental sequence, each being characterized by the development of a particular skill. The findings concerning morphological awareness, rather, suggest that multiple forms of awareness develop at the same time and are immediately used by children for spelling purposes.

Children's Sensitivity to Spelling Constraints

As discussed in the section 'What Does a Written Word Encode?,' a distinction can be made among three types of spelling constraints, besides the crucial determinants of phonological and morphological awareness: positional, phonemic, and graphemic constraints. Are children sensitive to these constraints and, if so, how early in their development?

Doublets have been used in several studies addressing the question whether young children make use of positional constraints. Doublets are reduplicated letters, like 'll' in 'mall.' The position of such doublets is restricted in many languages. For instance, in English they can occur in word-medial position ('muffin,' 'cellar') and word-final position ('mass,' 'stuff,') but never in word-initial position. In her 1993 paper, Treiman studied what children wrote in the classroom, i.e., she did not perform an experiment but collected authentic materials produced in a naturalistic setting. Interestingly, she found that children in Grade 1 already used consonant doublets and were sensitive to the positional constraint that exists in English: these children already used consonant doublets more often in medial and final word-positions than in word-initial positions. Importantly, they had caught on to this positional constraint without having been told about its existence: this type of spelling knowledge is not taught at schools. Hence, children's knowledge that consonant doublets are not used in word-initial position is the outcome of an implicit learning process.

In another study Treiman performed a controlled experiment (Cassar and Treiman, 1997) in which children in Grades 1 and 2 were studied with respect to their sensitivity to the position of consonant and vowel doublets. The authors used an orthographic constraints test, in which the child had to indicate the most wordlike item in a pair of two nonwords, e.g., 'baff' and 'bbaf.' The children more often rejected the nonword with a doublet in initial position, leading to the same conclusion as the naturalistic study: they had implicitly induced the positions at which English doublets can occur. The authors additionally observed that children had even more fine-grained knowledge about these doublets: they knew which vowels and consonants could appear in doublets and which could not. This was clear from the fact that they more often rejected nonexistent doublets than existing ones, when they both appeared in the same legal position (e.g., 'geed' was preferred over 'gaad,' 'yill' over 'yihh'). Again, they had implicitly derived this knowledge from the written material that they had been exposed to.

Again, similar findings were obtained in other languages, which obviously strengthens their reliability. In French, a consonant doublet can only occur in word-medial position ('ballon,' 'laisser'). Pacton et al. (2001) found that children in Grades 1 to 4 (note: even Grade 1) are already sensitive to this positional constraint: they judged nonwords as more wordlike when the doublet appeared in medial position than when it occurred in initial or final position (e.g., 'lammi' was preferred over 'llami'). They obtained the same result with frequent and infrequent or nonexisting doublets ('lammi'–'llami' vs 'xevvu'–'xxevu'), although children's performance was better on the frequent doublets. In the final section of this article, this will have serious implications for an important theoretical issue. At this point, it suffices to say that French children, like English children, apparently learn implicitly the positions in which consonant clusters can appear.

Space limitations make it impossible to cover more experiments addressing this issue. However, interested readers are referred to a study by Bernstein and Treiman (2001), in which the authors demonstrate that children prefer that an invented grapheme for a particular vowel sound be used in the same position as the one in which it was learnt. The study by Lehtonen (2006) on Finnish children's sensitivity to consonant doublets also deserves mention here. It leads to the same conclusion as all preceding experiments: very young children

(Grade 1) are already aware of the positional constraint regarding doublets in the written language.

Just as young children's early sensitivity to the morphological structure of words was a threat to stage models of spelling development, so is their early sensitivity to positional constraints to the use of doublets. In Grade 1, when they should be exclusively concerned with GP and PG mappings according to stage models, they are already sensitive to positional constraints as well. So, once more it appears that young children can make use of multiple information sources encoded in grapheme strings, at the same time.

Besides positional constraints there are phonemic and graphemic constraints. These will be treated together here. In a language like English there are dependencies between phonemes, such that one phoneme predicts the spelling of another. For instance, the sound 'k' is typically spelled as 'c' before many vowels, as in 'cost,' 'cat,' and 'cow,' but is spelled as 'k' before some vowels like 'e' and 'i' as in 'kettle' and 'kill.' Adults are sensitive to these dependencies. They rely on the vowel to spell word-final consonants or codas (Kessler and Treiman, 2004; Perry et al., 2002), but also to spell word-initial consonants or onsets (Kessler and Treiman, 2004). They also make use of consonants to spell vowels: Treiman et al. (2002) demonstrated that college students rely on the nature of codas and onsets when spelling vowels (see also Treiman and Kessler, 2006). Whereas it is interesting to observe that experienced spellers capitalize on dependencies between phonemes, the question at hand is whether young children are able to do the same.

Hayes et al. (2006) tackled this question by investigating how the performance of young children (Grade 2 (seven to eight years old), Grade 3, and Grade 5) in the spelling of codas and onsets related to the performance of college students. In the materials that they used, the coda's spellings were dependent on the preceding vowel: 'short' vowels being typically associated with what they called extended consonants ('pull'), and 'long' vowels with single consonants ('sail'). The materials focusing on the spelling of the onsets involved the spelling of the 'k' sound, which is typically spelled as 'k' before the sounds 'e' and '/i' ('kept,' 'kill') and as 'c' before other vowel sounds ('camp,' 'cool'). The tasks of the participants involved the spelling of pseudo-words and a forced-choice task between two pseudo-words, where the instruction was to indicate which item best represented a given pronunciation. The results indicated that Grade 2 children were already sensitive to the coda when determining the vowel spelling, although this sensitivity continued to increase with age. However, these same children were equally sensitive to the vowel as college students when the spelling of the onset was concerned.

Hayes et al.'s experiment had been designed to make it possible to disentangle the impact of the vowel's pronunciation (phonotactic effect) and its spelling (graphotactic effect). Hence, the data were analyzed to find out which factor was the determinant. The outcome was that the effects were graphotactic in nature. For instance, the spelling of the coda was not determined by vowel length (a phonological factor) but by the number of letters in the spelling of the vowel: "Each additional letter in the vowel spelling strongly decreased the likelihood that the coda spelling would be extended" (p. 36). The conclusion is that children as young as seven already make spontaneous use of graphotactic cues for determining the spelling of onsets and codas in a word. The authors explicitly point out that their finding is at odds with the predictions of stage models. According to such models these young children should only rely on GP and PG mappings. Once again, we come to the conclusion that young children are much more sensitive to other sources of information as well, and that stage models do not capture what is really going on during spelling development. (See also the study by Aaron et al. (1998) comparing the performance of hearing and deaf children on a memory test for pronounceable and non-pronounceable pseudo-words – 'doof,' 'kram' versus 'dfoo,' 'rmka' – which yielded the result that deaf children prefer the orthographically well-formed pseudo-words equally much as the hearing children, suggesting that these regularities are implicitly induced on the basis of sheer exposure.)

Finally, let us turn to children's sensitivity to the entire orthographic pattern of words: the full orthographic representation of the word. Martinet et al. (2004) report two experiments which clearly show that French children who had received literacy instruction for only three months were already sensitive to lexical knowledge, that is, the mental representation of a whole word's orthographic pattern. In one experiment the authors found that the children's spelling of irregular words was better when the words had a high-occurrence frequency in their reading materials than when their frequency was low. The critical irregular target grapheme was spelled more accurately in the high-frequency words, irrespective of whether the whole word was spelled correctly. The researchers found this pattern twice: after three and after nine months of literacy education. In another experiment, they showed that the children relied on stored knowledge of orthographic patterns when they had to spell French pseudo-words. Their spelling of pseudo-words like 'diRo,' a neighbor of the existing word 'siRo' ('sirop,' syrup), was more accurate than the spelling of control items like 'liko,' which has no neighbor. This finding illustrates that very young spellers draw on analogies with orthographic patterns of whole-word representations in their mental lexicon. These authors, too, present their findings as evidence against the predictions made by stage models: "Overall, the present results suggest that it is not appropriate to view spelling acquisition as a stage-like sequence where lexical knowledge establishes only in later stages of literacy acquisition once alphabetic skills are sufficiently well established. […] Such results are consistent with models of spelling development where lexical knowledge and alphabetic skills mutually influence and develop simultaneously from the very beginning of literacy acquisition" (p. B17).

Lété et al. (2008) arrive at a similar finding. In their regression study on the spelling performance of children in the First to Fifth Grades (see above), they also observed an effect of word frequency from the First Grade onwards. Even though the latter effect took a large jump between Grades 1 and 2, it was already present in First Grade children, just like in the Martinet et al. (2004) study. The word-frequency effect can be considered the fingerprint of lexical representations (representations in the mental lexicon,) and it appears that the ability to read and spell such representations is immediately established, even at the onset of learning.

When considering all study results pertaining to children's morphological sensitivity and their sensitivity to the different types of constraints that are encoded in written words, the only possible conclusion is that stage models do not offer a good description of their developmental trajectory when learning to spell. In contrast to what stage models proclaim, the evidence strongly suggests that children catch on to different types of information that are encoded in written words at a very young age (often from Grade 1 onwards) and use that information when they have to spell themselves – phonemes, morphemes, positional constraints, phonological and/or graphotactic constraints, and lexical knowledge (fully specified spelling patterns).

Factors Affecting the Spelling of Experienced Spellers

In this section, the focus will be on two types of errors that are still made by highly experienced writers: proximity errors and homophone intrusions. In order to discuss these error types the research that was performed in Fayol's research team (on French) and in my own team (on Dutch) will be discussed.

Fayol et al. (1994) set out from the observation that sometimes writers make spelling errors in which the spelling pattern of an inflected verb does not have the suffix spelling that it should have on the basis of the grammatical subject. Rather the suffix is spelled as if the immediately preceding noun were the grammatical subject. To make this less abstract, consider the sentence 'le chien des voisin arrive' ('the neighbor's dog arrives'). A typical spelling error for this sentence would be 'le chien des voisins arrivent,' in which the 'nt' spelling of the suffix (which marks the third person plural) seems to be induced by the preceding plural noun and has thus replaced the correct 'e' spelling (which marks the third person singular, as the grammatical subject – le voisin – is third person singular). Crucially, the two suffixes –'ent' and 'e' are homophonous in the language (both 'arrive' and 'arrivent' are pronounced (aRiv)) and thus do not facilitate spelling. Fayol et al. used a dual-task paradigm to induce such errors in a dictation task: subjects heard a sentence and simultaneously a series of clicks, when the audio fragment was played to them. They had to try to remember the sentence and at the same time count the number of clicks. Once the sentence was finished, they had to write it down and report the number of clicks they had heard. Using this paradigm, they could induce the type of errors illustrated above, which they called 'proximity errors': errors caused by the word in the immediate proximity of the target verb form. Hence, they could illustrate that when a computational procedure is called for in order to determine the spelling of a verb suffix, a situation of 'cognitive overload' can make it impossible to terminate this process. When this occurs, the spelling is determined by irrelevant information sources: in this case the preceding noun. The error is understandable: working-memory is overloaded so that the computational process cannot retrieve the grammatical subject in time, and the first noun that is encountered in working-memory is used for the purpose of determining the suffix spelling.

My colleagues and I observed a similar effect when studying errors in Dutch verb forms (Sandra et al., 1999). The spelling of these verb forms is very straightforward: a suffix is attached to the stem (concatenative morphology), the set of suffixes to choose from is very small, and children are taught these spelling rules since about age 10 (with continuing attention for errors on these forms throughout the educational system). Despite this, many errors are made when a verb form has a homophone in its inflectional paradigm, even by experienced spellers. For instance, the pronunciation of the third person singular, present tense form 'wordt' (becomes) is identical to the pronunciation of the first person singular, present tense form 'word' (become), because a stem-final 'd' is pronounced as 't.' This situation of homophony causes many intrusion errors. One of our findings was that more homophone intrusions were made when the distance (measured in number of words) between the grammatical subject and the inflected verb form increased. We made this observation in a speeded dictation task, administered to 18-year-old secondary school students. What is important for our current purpose is that this finding suggests the same conclusion as Fayol et al.'s proximity errors: when circumstances make it difficult for the computational process to determine the spelling of the suffix, this process cannot terminate, and produces an output such that the suffix spelling is determined on the basis of extraneous factors. In Fayol et al.'s study, the circumstances causing difficulties for the computational process were created by the dual-task paradigm. In our study these circumstances were created by the distance between the grammatical subject and the inflected verb form, which made the retrieval of the grammatical subject from working-memory more time-consuming than the time that was available for spelling the verb form. In Fayol et al.'s study, this situation of cognitive overload made it possible for the noun closest to the verb to determine the (wrong) suffix spelling, whereas in our own study the existence of a homophonic verb form made it possible to spell the wrong suffix.

The homophone intrusions mentioned above constituted an interesting error type in their own right, in the Sandra et al. experiments. More particularly, they were not randomly distributed but yielded a clear pattern: most homophone intrusions were instances where the higher-frequency form was spelled when the lower-frequency form was the actual target. Some Dutch verbs have a form ending in 'dt' (stem-final 'd' followed by the 't' suffix) that occurs with a higher frequency than its homophonous 'd' form (henceforth: DT dominant verbs), whereas other Dutch verbs have a 'd' form that occurs more frequently than its homophonous 'dt' form (henceforth: D dominant verbs). We found that DT dominant verbs cause more homophone intrusions when the 'd' form is the target form, whereas D dominant verbs cause more of these errors when the 'dt' form must be spelled. We interpreted this interaction effect between Dominance and Spelling Pattern as follows: whenever the computational process cannot determine the spelling of the inflectional suffix of a homophonous verb form (because it is a time-consuming process and writers often have insufficient time to retrieve the grammatical subject) a retrieval process accesses the two spelling patterns of the homophonic forms and gives priority to the higher-frequency form. Note that this means that fully regular, inflected verb forms are stored in the mental lexicon, even though this is not logically required, as their spelling patterns can be

computed on the basis of rules (see Sandra, 2010; Sandra and van Abbenyen, 2009 for more experiments addressing these issue; see Sandra, in press, for an overview of all experiments pertaining to these homophone intrusions).

Largy et al. (1996) reported similar findings in French. These authors presented spoken sentences to their subjects, e.g., 'Le chimiste prend des liquides. Il les filtre.' ('The chemist takes liquids. He filters them.') During the presentations of these sentences, subjects also heard a number of phonologically similar words and were told to remember both the sentence and the set of words (dual-task paradigm). The final verb form in the critical sentences was a singular form that was homophonous with a noun. The authors observed that many errors of the following type were made: 'Le chimiste prend les liquides. Il les filtres.' In these errors the last form ('filtres') is the plural of the homophonous noun 'filtre' ('filter'). This plural noun form is also homophonous with the verb form. These errors occurred particularly often, when the noun intruder had a higher frequency than the target verb form. Quite likely a double frequency effect is at work here: (1) the verb activates its homophonous noun, which is selected when it has a higher occurrence frequency than the verb (comparable to what happens in Dutch when two verb forms are homophonous, cf above), and (2) this homophonous noun is spelled in its plural form (remember that it has the same pronunciation in both singular and plural) because the previous word ('les') cannot only be used as a direct object in French (as in the target sentences) but also – and much more frequently – as the plural form of the definite article (i.e., 'the'). The joint operation of these two frequency-driven processes results in the errors of the above type. Importantly, we see that a similar error mechanism is at work in two different languages (Dutch and French): homophone intrusions are made in a regular inflectional domain as the result of the 'pressure' from the higher-frequency homophone.

As can be derived from the above, the spelling errors on regularly inflected verb forms in Dutch and French can be traced back to the same mental processes and representations: (1) the cognitive overload in working memory makes it impossible for the computational process to determine the suffix spelling in time, thus opening the door for extraneous influences (for instance, causing proximity errors), and (2) one of these extraneous influences is the operation of a retrieval mechanism when the regular verb form has a homophonic variant, a mechanism that provides access to two spelling patterns, gives priority to the higher-frequency one, and thus leads to more intrusions of the higher-frequency form than of the lower-frequency one (see Sandra and Fayol, 2003, for a systematic comparison between the two languages).

Abstract Rules or Statistical Learning?

A final question to be addressed is whether the findings in spelling research suggest that spellers rely on abstract representations of spelling rules or depend on a form of statistical learning. A favorite technique for studying this question is to present words or pseudo-words that (1) require the application of a spelling rule but (2) also contain a particular spelling cue, i.e., a cue that suggests a particular spelling, which need not correspond to the spelling required by the rule. The rationale behind this technique is that such spelling cues should be totally irrelevant, as a rule, by definition, makes total abstraction of spelling cues. Indeed, a rule applies to abstract categories (like noun, verb, etc.). Hence, any interaction between spelling rules and spelling cues would suggest that spellers do not rely on an abstract rule when spelling.

Kemp and Bryant (2003) studied the spelling of English plurals, using real words and pseudo-words. They focused on the spelling of the 'z' sound when it signals plurality (e.g., 'tears'). It is clear that the spelling rule for plural formation abstracts away from the fact that the final sound is 'z.' The English plural suffix is always spelled as 's.' Moreover the rule also abstracts away from the preceding graphemes. In order to find out whether spellers applied an abstract rule or were also affected by the orthographic context, two types of roots and pseudo-roots were studied: those ending in a voiced consonant and those ending in a vowel. Whereas the sound 'z' preceded by a voiced consonant must be spelled as 's' – English consonants cannot be followed by the letter 'z' (e.g., orthographic clusters like 'bz,' 'dz,' … do not exist in word-final position) – the sound 'z' preceded by a long vowel allows other spellings as well (e.g., 'bees,' 'buzz,' 'please,' 'breeze'). The results showed that English children, both good and poor spellers, made more spelling mistakes on the plurals of roots and pseudo-roots ending in a long vowel. This strongly suggests that when spelling a plural form, English children do not rely on an abstract rule. If they had done that in the experiment, they would have been insensitive to the preceding grapheme, as the spelling rule ('add s') applies to the abstract category 'noun' and is, hence, indifferent to graphotactic cues. It seems that multiple sources of information are unconsciously combined when spelling the plural of a (pseudo-) word.

Even more surpirsing is Deacon and Pacton's finding (2006, mentioned in Pacton and Deacon, 2008) that this effect is very persistent. They ran a similar experiment but used adults with tertiary education as their subjects this time. They presented pseudo-nouns in sentence contexts and in isolation. Here too a graphotactic effect emerged in the data: fewer 's' spellings occurred after a long vowel than after a consonant. Apparently (and surprisingly) even experienced spellers cannot avoid interference from irrelevant graphotactic cues.

Pacton et al. (2005) arrived at a similar conclusion in French. Using French children (ages: 7–11) and adults, they studied how the diminutive suffix, which sounds like [et], was spelled, depending on the preceding letter. The suffix should always be spelled as 'ette,' no matter which letter precedes it. However, Pacton et al. wondered whether the fact that this suffix occurs much more frequently after the letter 'r' than after the letter 'f' in the set of French diminutives would have an effect on subjects' spelling performance. Pseudo-words were used (e.g., 'vitar,' 'vitaf'). As in the English studies on the spelling of the plural suffix 's,' the findings indicated that the rule was not applied in an abstract way, i.e., by ignoring the irrelevant preceding letter. In all subject groups, including the group of adults, a sensitivity to the graphotactic context was found: the correct spelling 'ette' was produced more often in words ending in the letter 'r' ('virarette') than in words ending in the letter 'f' ('vitafette'). Hence,

spellers – even experienced ones – appear unable to ignore the preceding orthographic context and are more prepared to spell 'ette' after the letter 'r' (thus producing a high-frequency orthographic sequence in the set of diminutive words) than after the letter 'f.'

Pacton et al. (2001) provided particularly convincing evidence that spellers do not make use of abstract rules. When studying children's sensitivity to the positional constraints on the use of French consonant doublets (see above), the researchers not only found that children develop a very early sensitivity to the fact that such doublets can only occur in word-medial position; they also found that this positional-sensitivity dropped when consonant doublets were used that do not occur in French. Whereas such doublets obviously must have given rise to strange letter sequences, there should have been no drop in performance if the children had used an abstract rule. Indeed, such a rule, by definition, applies to any consonant doublet: familiar or novel. In other words, an abstract rule guarantees a seamless transfer to novel doublets – which was not the case.

The bottom line of these (and other) experiments of this type can be briefly summarized: spellers do not appeal to abstract spelling rules while ignoring all kinds of information that are irrelevant for rule application. Rather they seem to pool all information sources related to the spelling of a sound. One of the most surprising findings in this connection is that even experienced spellers do not succeed in 'switching off' these irrelevant spelling cues and make spelling errors as a result of it. To be honest, these findings do not reject the existence of abstract rule representations. That is only one possibility. Another is that spellers have such representations but cannot avoid other information sources competing with these rules, and such competition causes spelling errors. Hence, the question whether abstract rules are a chimera or not is still unsolved. However, it is already astonishing to observe, across different experiments, that even experienced spellers are unable to ignore irrelevant spelling cues when they have to apply a spelling rule.

Abstract

Herbert Spencer was the best-read sociologist of the late nineteenth and early twentieth centuries. He wrote major treatises on biology, psychology, sociology, and ethics as part of his lifetime project of forging a *Synthetic Philosophy* that would integrate science and ethics under a law of evolution that was loosely built from ideas in physics. His sociological work emphasized developing laws of human organization as societies differentiate in response to growth. He illustrated these laws with cross-cultural and comparative data. In developing his laws of societal evolution, Spencer founded functionalism, a school of thought that analyzes how basic needs for survival generate selection pressures for structures operating along four fundamental dimensions of societal existence: production, reproduction, regulation (coordination through power), and distribution (of information, people and resources). Spencer's ideas continue to inform modern sociology, but often the origin of these ideas as coming from Spencer is lost.

Herbert Spencer was born on 27 April 1820 in Derby, UK, and after a long and distinguished career as a major intellectual, he died on 8 December 1903 in Brighton, UK. During Spencer's childhood, he was privately tutored, first by his father and then, after the age of 13, by his uncle in Bath. Thus, Spencer received little formal education outside of his family, although his in-depth tutelage in mathematics and science was sufficient for him to contemplate as a relatively young man a grand Synthetic Philosophy in which a few general or 'first principles' (1862) could be used to explain the operative dynamics of physical science, biology (1864–67), psychology (1855), sociology (1874–96), and ethics (1892–98). He also was a moral crusader, writing important philosophical statements on such topics as education (1860) and social wellbeing (1850, 1892–98).

Spencer's sociology comes late in his career, beginning with a methodological treatise on sources of bias (Spencer, 1873), continuing with an effort to systematically array cross-cultural and comparative data (Spencer, 1873–34), and culminating with the use of data to illustrate the basic laws of sociology (Spencer, 1898b [1874–96]). In this article, the goal is to see how Spencer's grand scheme developed and how it evolved into a profoundly important sociology (for a comprehensive listing of primary works by Spencer and of works on Spencer, see Perrin (1993)).

Biographical Influences on Spencer's Sociology

Several important aspects of Spencer's biography are important in examining his impact on social science. First, he never held an academic position, and hence, he did not have any students to carry forth his work after his death, although the wealth inherited from his uncle and from his book sales did allow him to commission other academics to perform research and, even after his death, to continue to completion the volumes of his *Descriptive Sociology* (Spencer, 1873–34). Second, he lived an extremely spartan life, and yet at the same time, he interacted in London Clubs and various assemblies with the elite scientists and intellectuals of his time. Indeed, it is from these scholars – figures such as Thomas Huxley, Joseph Hooker, John Tyndall, and even Charles Darwin – that Spencer absorbed much of his knowledge about current discoveries in science. Third, Spencer was immensely popular in his time. His works generally came out in serial form in magazines and private subscriptions, later being packaged as whole books which sold more than 400 000 copies during Spencer's lifetime. Yet, despite his enormous popularity, Spencer was an enigma because he had no formal academic affiliation and because he lived a very private and, it appears, rather neurotic life punctuated by hypochondria. Yet, in all his works, several key influences are evident. Reading Thomas Malthus, Karl Erst von Baer, and Charles Darwin gave Spencer a view of the universe as evolving from simple to more complex through competition; extensive reading of the physical sciences gave Spencer a post-Newtonian conception of science, a view emphasizing that universal laws could explain all domains of the universe; and reading of Auguste Comte also gave Spencer a view of sociology as the search for general laws as well as a conception of social organisms as having structures devoted to meeting basic needs and of societal evolution as involving an increasing complexity of structures meeting these needs. Spencer (1968 [1864]) was, however, always rather defensive about perceptions of Comte's influence on him. Out of this mix of influences came Spencer's grand Synthetic Philosophy that was to unify physical science, psychology, biology, sociology, and ethics under first principles borrowed from the physics of Spencer's time.

The Stigma of Spencer's Moral Philosophy

Spencer's moral philosophy is one reason that his intellectual star began to fade in the early twentieth century. In his first major work, *Social Statics* (1850), almost a decade before Darwin published *On the Origin of Species*, Spencer coined the phrase 'the survival of the fittest' that was to haunt him for the rest of his career. The more general philosophy in this work simply argued that individuals should be free to pursue their happiness, as long as they do not abridge the rights of others to do the same, although there was a hard edge to this philosophy emphasizing that the less fit should not be supported by the state. Spencer (1904) complained bitterly in his autobiography

about how he had become type cast as a result of this first book, but it is hard to feel sorry for him because he made the same 'libertarian' (in today's vocabulary) statements in his last work, *The Principles of Ethics*. For a discipline such as sociology, which is liberal in the twentieth century as opposed to the nineteenth century sense where freedom of the individual and lack of governmental activism are emphasized, this libertarian-sounding ideology has always worked to obscure the important contributions of Spencer to sociology.

The 'First' or 'Cardinal' Principles

Spencer's use of the physics of his time to formulate his 'cardinal principles' is now rather dated. Spencer postulated three basic principles: (1) the indestructibility of matter, (2) the continuity of motion in a given direction, and (3) the persistence of force behind movement of matter. From these general principles, three corollaries were derived: (4) the transferability of force from one type of matter and motion to another, (5) the tendency of motion to pass along the line of least resistance, and (6) the rhythmic nature of motion. From these principles, Spencer (1880[1862], p. 286) formulated his famous law of evolution as 'change from a less coherent form to a more coherent form, consequently on the dissipation of motion and integration of matter.' This law was presumed to apply to the evolution of celestial bodies, chemical compounds, organisms, and superorganic bodies (organization of organisms). Spencer was, therefore, the world's first general systems theorist.

The first or cardinal principles are less interesting than what Spencer did with them as he applied them to organic and superorganic evolution. In *Principles of Biology*, Spencer used the first principles to formulate the cornerstone of his biology and sociology: increasing size of an organic or superorganic mass requires an exponential differentiation of the structure necessary to support the larger mass. This principle is still used in biology, although its origins to Spencer are long forgotten; the principle is employed in sociology to study differentiation at all levels of social organization, with only a vague sense that this idea comes from Spencer. In many ways, this theoretical cornerstone of Spencer's Synthetic Philosophy actually comes more from his training and brief practice as an engineer than it does from his first principles; for within engineering it is well established that larger structures require more complex systems of support.

Spencer's star faded long ago in biology, and there is only a hint of his influence in education and philosophy today. Where Spencer still remains a figure deserving of at least mention, often in a somewhat derisive way, is in sociology. In order to appreciate what Spencer's legacy is today, we must review his contributions to sociology, where he still lives on as a marginal figure in sociology's pantheon of great masters that includes such giants as Karl Marx, Max Weber, Émile Durkheim, and George Herbert Mead.

Spencer's Functionalism

Spencer is famous for his 'organismic analogy' in which he lists in a more formal manner than Comte before him the parallel principles of organization between organic and superorganic bodies. But this analogy is often given too much emphasis in commentaries on Spencer because it hides a rather sophisticated functionalism. For Spencer, all superorganic systems composed of organic units must meet three basic requisites if they are to survive: (1) operation or (a) production of life-sustaining substances and (b) reproduction of units; (2) regulation or coordination and control of units; and (3) distribution or movement of necessary information and substances among units. Populations which cannot meet these requisites will experience 'dissolution,' a notion first developed in *First Principles* (1880 [1862]). Thus, Spencer did not view evolution as an inevitable process of movement from simple to complex as populations sought to resolve problems of operation, regulation, and distribution; on the contrary, he recognized that societies often disintegrate. In this discussion of functional requisites, Spencer introduces two conceptions of 'selection.' On the one hand, Spencer argued that evolution of societies tends to increase complexity because, as societies come into conflict, the more complex and better organized generally will prevail, thereby ratcheting up the overall level of societal complexity. This argument is one of the first 'group selectionist' statements presented in either biology or the social sciences. On the other hand, there is another kind of selection which is at the core of all functionalist arguments. This selection occurs alongside Darwinian selection and revolves around problems and crises in production, reproduction, regulation, and distribution. When problems in any of these spheres emerge, they set into motion efforts to search for solutions by goal-seeking social units. Thus, social selection in superorganic systems is not blind because the very units subject to selection can change their structure and thereby avoid being selected out. Spencer argues that most selection in sociocultural systems is of this second type, where problems of adaptation activate efforts to resolve crises with respect to production, reproduction, regulation, and distribution.

Since these requisites are the essential problems of survival in all superorganic systems, including both human and nonhuman societies, differentiation of structure during the course of evolution will revolve around these four axes. First will come differentiation of productive structures, followed by differentiation of reproductive units. This increased differentiation along these axes will generate selection pressures for their coordination and control, leading to the elaboration of political systems. As differentiation of operative and regulatory units occurs, new systems of distribution become necessary if dissolution is to be avoided. As these new systems of distribution emerge, e.g., markets, communication, and transportation infrastructures, they create new selection pressures for their regulation while at the same time providing positive feedback for further differentiation of production and, later, reproduction. Thus, movement of superorganic systems from simple to complex forms revolves around selection pressures along the axes of operation, regulation, and distribution as well as around the mutual feedforward and feedback effects of differentiation along one axis on the other axes. This kind of analysis is far more sophisticated than the typical commentary on functionalism acknowledges.

Spencer's substantive sociology also offers some very important models of system dynamics. One element of these models follows from the basic law: as a population grows, the

increasing size generates escalated logistical loads for operation, regulation, and distribution which, in turn, set off selection pressures in the manner described above. Spencer's political sociology should be viewed in this context. For Spencer, once power is concentrated, this initial concentration will be used to gain even more regulatory control. As power becomes more concentrated, inequalities will escalate as those with power extract an ever-greater proportion of a population's resources. As inequalities increase, disintegrative pressures mount leading to the concentration of more power to suppress the potential conflict that always inheres in inequality; and as this process is iterated, system dissolution is likely. Geopolitics are also involved in these dynamics, in several senses. First, elites in the regulatory sector often engage in war to secure the resources of other populations which only increases the concentration of power and the scale and scope of inequalities. Second, such war-making efforts often distract subordinates in a system of inequality, at least for a time, from their true interests in changing the system of power generating inequality. Third, when power becomes too concentrated, resistance to this power inevitably increases, often leading to protest movements and other actions that lead to some deconcentration of power. Yet, the longer deconcentrated power lasts, problems of coordination and control escalate, creating selection pressures for reconsolidation of power. Societies thus cycle between concentrated profiles of power (what Spencer termed the 'militant') and deconcentrated power (what Spencer called 'industrial' profiles) – a line of analysis that predates Vilfredo Pareto's discussion of the circulation of elites.

The Data Behind Spencer's Sociology

These lines of argument have a very contemporary ring to them, and they can be found throughout Spencer's *Principles of Sociology*. Moreover, they are rather easily converted into laws or principles since this is how Spencer thought (see Turner, 1985, for an effort to extract the principles from Spencer's work). One of the criticisms of Spencer's functionalism is that it is so speculative; while this may be so, Spencer also amassed enormous amounts of data to support his theoretical speculations. Indeed, the reason that Spencer's *Principles of Sociology* is such a long work is that it is filled with data. In fact, many scholars complained at its first publication in serial form and later as a three-volume book that the analytical ideas get lost in all the data. Thus, Spencer assembled data far in excess of almost any other sociologist in the history of the discipline. He hired professional academics to gather historical and ethnographic information, ordering it into categories that followed from his general functionalist scheme. There are many tragedies in the contemporary view of Spencer, but none is greater than the loss of what Spencer began in the 1860s and first published in 1873 as the inaugural volume of his *Descriptive Sociology* (the last volume was published in 1934).

Spencer was the first to execute what was later done by those assembling the Human Relations Area Files (HRAF) (e.g., Murdock 1953). Spencer recognized that in order to make generalizations about human societies, a large comparative database was necessary. But these data had to be arrayed so that they could be compared, leading Spencer to develop a category system for recording the data being assembled by professional academics. The result was the multivolume *Descriptive Sociology* (1873–34) which arrays data historically for those societies that have a written history and cross-sectionally for those less developed societies without a written history. The publication of these oversized volumes has been completely lost to modern social science, but if Spencer's lead had been followed by others in the nineteenth century, all social science would have a much firmer empirical base than is provided by HRAF. At the very time Spencer was assembling available information on 'primitive' societies, these societies were being changed or destroyed by colonial forces, with the result that by the time anthropologists began to study them in detail in the 1930s, their pristine character had long been compromised. *Descriptive Sociology* could have been Spencer's greatest legacy, but like so much of his work, the contemporary world remains largely ignorant of his efforts to create a database for assessing the plausibility of his theories.

What Might have Been, and What Can Still Be

By the time of Spencer's death in 1903, his star had already begun to fade in intellectual circles. One reason for this decline can be attributed to Spencer as a lone scholar working outside of academia. Without students to carry on his work and without a school of thought institutionalized in academia, there was no one and no place to carry forward Spencerian sociology. Work still continued on *Descriptive Sociology* but this was much narrower in scope than Spencer's philosophy or even his sociology, and moreover, most of this work was contracted to scholars who were not committed to Spencer's grand scheme. So, when Talcott Parsons (1937) asked 'who now reads Spencer,' the answer was not very many scholars inside or outside of sociology. Spencer's star had fallen at the same time that evolutionary thinking came under attack in anthropology, and with no one to defend Spencer's sociology, he fell into obscurity. Yet, let us imagine for a moment what might have happened if Spencer had been defended by students or had established a school entrenched in academia like Durkheim's *année* school in France. In conducting this thought experiment, we can come to appreciate not only what might have been, but more fundamentally, what is still available in Spencer's legacy.

The first legacy would have been a Human Relations Area Files that came earlier, before colonialism completely destroyed indigenous populations. Moreover, sociology would have had a database that was comparative in several senses: the data would have been arrayed in common categories that are more sophisticated than George P. Murdock's (1953) HRAF; the data would have been both historical and ethnographic and would have allowed systematic comparisons of different types of societies at any point in time. Only in the last three decades has comparative-historical and ethnographic data been reintroduced back into sociology and, ironically, this reintroduction has been part of a movement to rekindle interest in the very evolutionary thinking that was used to discredit Spencer.

The second legacy is that the evolutionary paradigm would have survived and avoided the 50-year hiatus. Stage models have utility in sociological analysis, as has been demonstrated in the work of Gerhard Lenski (1966), Stephen K. Sanderson (1995), Jonathan Turner (1984, 1997), and others in recent

years. Moreover, adopting Spencer's views on evolution would have avoided the view of evolution as inexorable, since dissolution would be a prominent point of analysis as would dialectical cycles within either evolution or dissolution.

A third legacy would have been a sophisticated functionalism that, unlike mid-twentieth century approaches, sought to articulate theoretical principles about the dynamics of social processes rather than simply cross-tabulate lists of functional requisites with lists of social processes. Functionalism fell into disuse not so much because it was dead wrong but because it was not done well. A reading of Spencer would have led the way to a functionalism that does not build conceptual schemes as much as highlight fundamental forces whose operative dynamics can be captured in theoretical principles.

A fourth legacy would have been a sociology that did not lose sight of its status as a science in which the goal is to generate theoretical principles that explain the operative dynamics of the social universe. Spencer's methodological treatise and his articulation of actual laws of human organization would have sustained the discipline better than Marx, Weber, Simmel, or Durkheim could, as various antiscience and excessively relativistic movements have come and gone for the whole of the twentieth century in sociology.

A fifth legacy would have been the actual substance of Spencerian sociology. Imagine if sociologists had mined *The Principles of Sociology* for insights into human organization with the same intensity as we have delved into Marx, Durkheim, Weber, or Mead. Spencer provided not only highly abstract theoretical principles but also many principles about the operation of stratification systems, polity, kinship, religion, economy, markets, ceremonies, professions, organizations, education, and many other key structures, and he documented these generalizations with copious amounts of historical, ethnographic, and for his time, contemporary data. The sociology of major institutions (e.g., family, education, religion, etc.) would be less parochial and descriptive than it is today because it would examine the dynamics of the institution with ethnographic as well as historical-comparative data organized by basic theoretical principles.

A sixth legacy would have been the continued connection between biology and sociology. This connection has only recently been revived along all the fronts found in Spencer's work. There is the ecological approach emphasizing Darwinian dynamics that Spencer saw before Darwin and that are now used to examine the relations between resources niches and a wide variety of social processes. Indeed, there is the revival of selection arguments in general (e.g., Runciman, 1998), and moreover, an effort to move beyond Darwinian selection to considerations of group selection (e.g., Sober and Wilson, 1998) and Lamarckian processes so evident in Spencerian sociology (Turner, 1995).

A seventh legacy is a political sociology that connects stratification processes within society to geopolitical dynamics in world systems. At the core of Spencer's sociology is a concern with power that is the equal of that to be found in either Marx or Weber. One of Spencer's main explanatory variables is how the concentration of power alters all other social processes, especially stratification and institutional systems, and his analysis of how war and commerce in the world system are implicated in power dynamics would not only have supplemented Marx and Weber but would have led to the emergence of world systems theory at the beginning rather than at the three-quarters mark of the twentieth century (e.g., Wallerstein, 1974).

An eighth legacy is the emphasis on the fundamental relation between size, differentiation, and modes of integration. Much of this legacy was rediscovered in the mid-twentieth century in organizational studies on administrative intensity, but the basic dynamic operates at all levels of society. If sociologists had pursued Spencer's lead and focused in 1910 on this fundamental relationship in the social universe, not only would organizational studies been moved forward at an earlier point in history but also other social units might well have been analyzed for how these relations among size, differentiation, and integration play themselves out.

These eight lines of thinking that are part of Spencerian sociology were available to all sociologists by the early 1890s. In a sense we have squandered this incredible legacy, but it is not too late. The above thought experiment can be more than an intellectual exercise in the history of ideas. A reading of Spencer today can still inform sociology. There are gems of insight to be discovered and used to analyze societies in almost everything Spencer wrote. They simply sit there on library shelves, waiting to be used by scholars in the twenty-first century. There is probably little more to be gleaned from poring over the texts of others in sociology's early pantheon, but the neglect of Spencer for the whole of the twentieth century provides a rich resource for the twenty-first century.

Abstract

This article reviews the major scientific contributions of Nobel Laureate Roger W. Sperry, whose collective studies revolutionized our understanding of brain function. His early work, beginning in the 1940s, culminated with the publication of his *Chemoaffinity Theory* in the mid-1960s. This theory holds that neural networks are determined by a genetically controlled chemical code. The 'hard-wired' nature of this network results in a specific, highly adaptive range of behavior, which is unalterable by training. His next series of studies related to the anatomic basis of neocortical information processing. He was able to show, in several simple, yet ingenious experiments, that perception is dependent upon vertically oriented cortical columns. The work, which resulted in the Nobel Prize (1981), relates to the function of connections between the 2 brain halves, and the lateralization of cognitive abilities in humans. These studies led to his final major contribution, which holds that consciousness is an 'emergent state' resulting from, but greater than, the sum of all the neuronal activity which produced it. This conscious state – the mind – continuously feeds back onto the brain by way of 'downward causation,' resulting in a continuous, highly dynamic process of change in neuronal activity from one moment to the next.

Roger W. Sperry, scientist, teacher, philosopher, and humanitarian was born in Hartford, Connecticut, USA on August 20, 1913. He was married to Norma Dupree in 1949; they had 2 children. He died on April 17, 1994.

The diversity of Sperry's interests is not only reflected in his distinguished academic career, but also in his avocations. In addition to his major contributions to our understanding of brain structure and function, he was an unusually talented artist, sculptor, and paleontologist. His multiple talents across many areas attracted a constant stream of graduate students, postdoctoral fellows, and visiting scientists to his Psychobiology Unit at Caltech for four decades.

Sperry's scientific contributions centered on four major areas, the first of–which began in the early 1940s, while he was still a graduate student in Paul Weiss' laboratory at the University of Chicago. Paul Weiss, whose views dominated the field of neural development at the time, held that the leading tips of growing neurons solely responded to local mechanical stimuli, and were in no way influenced by distant chemical cues. His numerous tissue culture studies had essentially closed the door on any possibility of chemical influences on neuronal growth. Weiss also held that the normal function of the nervous system was in no way dependent upon the precise patterns of neuronal connections. One example of this, according to him, was that when motor nerves were transplanted into any foreign muscle, normal movements would eventually occur after a period of training.

Sperry, as was to become his custom, challenged these ideas, and designed a typically simple, but ingenious experiment to test whether or not specific nerve connections are critical for normal function. Using rats, he transplanted motor nerves from leg muscles of one side to muscles of the opposite side, then tested their movements after the new nerve-muscle connections were established. Function was found to be severely impaired, and no amount of training could correct it (Sperry, 1945). These results also had important implications for humans. Neurosurgeons at the time were transplanting nerves in wounded war veterans in attempts to help them regain digit and limb movements, which had been lost as a result of war injuries. In spite of extensive post-surgical training, these transplants met with little success. During his military service with the Office of Scientific Research and Development (1942–45), Sperry, along with Weiss, showed that surgical transplantation of nerves to antagonistic muscle groups followed by intensive training simply did not work because transplanted nerves were inherently different from the nerves which normally innervated those muscles. This finding resulted in significant modifications of treatment procedures, thus saving a great deal of time, frustration, and money.

During this same period it was reported that if the optic nerve were sectioned in amphibians, optic axons would regenerate into the brain, and normal function would be restored. Sperry immediately recognized that this finding offered the perfect opportunity to test his ideas regarding functional specificity and the possible role of chemical influences on neuronal growth patterns. He first confirmed the above results (Sperry, 1950), then once again designed a brilliantly simple study – the now classic eye rotation experiment in the frog – to test his ideas. A hungry frog will accurately strike out with its tongue to obtain a fly held in front of it. Sperry sectioned the optic nerves of normal frogs, and rotated the eyeballs by 180 degrees. After regeneration had taken place and connections were reestablished in that part of the brain which is known to receive visual fiber input (an area called the optic tectum), he tested the frog's ability to capture a fly. The premise was that if the retinal axons had regrown into their normal sites of termination (in spite of the fact that the eye had been left/right reversed and turned upside-down), the frog should misdirect its strike by 180 degrees in any direction. If, however, the regenerating optic fibers disregarded their original target sites and established new central connections corresponding to the rotated eyes, the frog would be capable of striking accurately at the target fly. The answer was unequivocal. When the fly was held 90 degrees to the frog's right, it struck out 90 degrees to its left–180 degrees out of phase. The same result was obtained for all directions – left, right, up, down. The strike was always 180 degrees off, and no amount of retraining could correct it. The conclusion from both of the above lines of evidence was

clear: peripheral nerves cannot be 'forced' to establish connections with foreign muscles, and centrally regenerating nerves will reconnect to their original sites, in spite of radical alterations of their starting positions. A number of other rerouting studies were carried out, each of them supporting the basic premise, which Sperry termed 'the chemoaffinity hypothesis.' Briefly stated, the growth and development of a pre-patterned neural network is determined by a genetically controlled chemical code, and the 'hard-wired' nature of this network results in a specific, highly adaptive range of behavior which is unalterable by training. Other studies over the next 20 years, using neuroanatomical and neurophysiological approaches, provided confirmation of this hypothesis. Attardi and Sperry (1963) provided further, histological confirmation by showing that regenerating retinal axons in the goldfish would always regrow to their original terminal sites in the brain.

Two major theoretical papers were published by Sperry in the mid-1960s (see Voneida, 1997; Sperry, 1965a), in which he precisely described his chemoaffinity theory. In spite of numerous attempts over the next three decades to disprove the theory, it has prevailed with only slight variations and elaboration of the basic premise. It was primarily this work, begun as a predoctoral student in 1938 and pursued through the early 1960s that resulted in his election to the National Academy of Sciences.

A second major area of Sperry's work deals with cortical organization related to higher cognitive function in mammals. He joined the renowned psychobiologist Karl Lashley at Harvard for his postdoctoral work, where he began a new series of studies on the role of electrical fields in neocortical function. He was not comfortable with the idea that electrical fields or waves acting in a volume conductor (the brain) are critical for neocortical processing. His first study to challenge this was published in the late 1940s (see Sperry, 1947). Here he demonstrated that motor coordination in monkeys remained virtually unaffected after multiple transections of sensorimotor cortex. He later confirmed this by demonstrating that neither cortical cuts, the insertion of numerous short circuiting wires or insulating plates into the cortex had any adverse effect on cortical function. These studies demonstrated that perception is dependent upon vertically oriented afferent and efferent cortical axons, predating the discovery of vertically oriented cortical columns. Sperry's premise was based on his keen understanding of neuroanatomy and neurophysiology, including the work of Santiago Ramon y Cajal and Lorente' de No, both of whom had demonstrated the importance of radial cortical connections to cortical function.

Thus, in a few carefully conducted experiments, Sperry had once again upset two major theories of brain function, Gestalt electric field theory of perception and the reduplicated interference pattern hypothesis. Indeed, when the renowned neuroembryologist Viktor Hamburger presented Sperry with the Ralph Gerard Award from the Society of Neuroscience in 1979, he proclaimed, 'I know of nobody else who has disposed of cherished ideas of both his doctoral and his postdoctoral sponsor, both at that time the acknowledged leaders in their fields.'

Sperry's third major contribution relates to the function of neuronal connections between the two brain halves (called commissures), interhemispheric communication, and lateralization of cognitive abilities in humans. Most of this work was done at Caltech, where he served as Hixon Professor of Psychobiology from 1954 to 1994. It was these studies, carried out between the mid-1950s through the 1970s (see Sperry, 1981), which resulted in the Nobel Prize in Physiology and Medicine (shared with Hubel and Wiesel) in 1981. The early studies, carried out by Sperry and his students at Caltech from the mid-1950s through to the 1960s, elegantly elucidated some of the major functions of interhemispheric connections in memory transfer and eye-hand coordination. Restriction of sensory input to one brain hemisphere in animals having undergone surgical separation of the two brain halves was shown to limit the learning of various tasks to the 'input' hemisphere; the opposite side was capable of learning, but remained naive to those tasks until trained. Learning curves for each brain half were virtually identical; it was as if two separate brains were housed within a single cranial vault. It was during this period that he also began his work on the lateralization of cerebral function in humans. Neurosurgeons Philip Vogel and Joseph Bogen had performed a surgical section of the major pathway connecting the two brain halves on a World War II veteran who was suffering from progressively worsening epileptic seizures. Working in collaboration with Vogel and Bogen, Sperry and his students began a series of tests directed at understanding the effects of this surgical hemispheric separation on human perception, speech, and motor control. The work involved comparisons of cognitive abilities between the two separated brain halves, demonstrating differences theretofore unrecognized.

For the next 20 years, the work of Sperry and his collaborators revolutionized our understanding of brain function. Prior to this time, the right hemisphere had been virtually neglected by neuroscientists. At best, it was felt to play only a minor role in human cognition, with all major cognitive functions emanating from the left, or dominant half. As a result of Sperry's research, the right hemisphere gained its long overdue recognition as a full partner to the left, playing a major role in holistic, parallel, and spatial abilities. The left brain half was found to be superior to the right in tasks involving analytical, sequential, and linguistic processing. Perhaps most importantly, however, Sperry demonstrated that the combined effects of bihemispheric activity amounted to much more than the simple additive effects of the two separate hemispheres, and led him into the area of his fourth and final major contribution; namely, the relationship between brain and mind, science and values.

Sperry began thinking and writing about the subjective aspects of brain function as early as the late 1950s. In 1959, for example, as part of the discussion at the Josiah Macy Conference on the Central Nervous System and Behavior, he stated that he had never been entirely satisfied with the behaviorists' interpretation of brain function in purely objective terms, with no reference whatsoever to subjective experience. He pointed out that this does not mean that we should abandon the objective approach; it simply means that we should also include subjective experience in our working models of the brain. Again, in his 1965 paper, *Merging Mind, Brain, and Human Values* (see Sperry, 1965b), he reinforces this thesis in his declaration that conscious forces must be included in any model or description of brain function, stating that in this

model, '... conscious mental psychic forces are recognized to be the crowning achievement of some five hundred million years or more of evolution.'

Sperry continued to think and write about the mind, consciousness, and their relationship to human values right up to the end of his life. He postulated that the mind is an emergent property of brain function, and like most emergent properties, bears little resemblance to the hundreds of millions of neurons in the central nervous system. He emphasized that while the mind is not the *same* as the brain, it is *dependent* upon it. This point is an important one, for it separates Sperry's views from the philosophical concept of dualism. Thus brain and mind are by no means separate entities, but function rather as coexistant partners through the processes of emergence and downward causation, or feedback. Taken together, these two properties result in a continuous, highly dynamic process of change from one moment to the next, drawing constantly on previous experiences by way of learning and memory, whether they occurred in the distant past or only moments ago. He strongly argued against reductionism, which dominated psychological thinking during the first half of the twentieth century. He believed that reducing consciousness to its separate components obliterates the emergent properties of mind, with '... *all its great power and uniqueness*' (see Sperry, 1993).

Sperry then elevated his concept of mind as an emergent property of brain activity to a global level, stating that:

> The new paradigm affirms that the world we live in is driven not solely by mindless physical forces but more crucially, by subjective human values. Human values become the underlying key to world change (see Voneida 1997).

He urged his scientific colleagues to use the very unique and powerful forces of mind and consciousness toward improving and preserving the quality of life on our planet, rather than the reverse. His urgent appeal finally began to be heard when his long-term friend and colleague, Professor Rita Levi-Montalcini, herself a Nobel Laureate, convened the International Conference of Human Duties at the University of Trieste in November, 1992, to discuss these ideas in greater detail. Regrettably, Sperry's illness prevented him from attending the first meeting, which included 10 Nobel Laureates and numerous others, representing such widespread disciplines as neurobiology, chemistry, physics, economics, and theology. This conference led to the formation of The International Council of Human Duties, which formulated 'The Declaration of Human Duties' in 1994. The document has been published (Trieste Declaration, 1997) and forwarded to The United Nations, for its consideration as a corollary to the 'Declaration of Human Rights.'

Sperry's thinking about subjective experience, consciousness, the mind and human values were crystallized in his paper 'The Impact and Promise of the Cognitive Revolution' (Sperry, 1993), delivered at the American Psychological Association's centennial meeting in 1993. It expressed his great hope and sincere belief that if we humans could simply be persuaded to put our collective minds together and to use the enormous emergent power that they are capable of generating, we might very well begin the new millennium by not only improving the quality of life on the planet, but also by significantly increasing our chances for survival.

Abstract

This article gives a short overview of the main manifestations of spirit possession. It outlines previous theoretical approaches, like psychological, sociological, and hermeneutical interpretations, but focuses predominantly on newer developments. These are the important roles of spirit possession in coping with the consequences of war, especially in postsocialist countries as well as in the increasing exchange of knowledge and import of spirit performances between diaspora communities and their countries of origin.

Despite its prohibition by some colonial governments and processes of modernization and secularization, spirit possession remains a vital force in the religious landscape of African, Asian, and Latin American countries. It is at present on a high which refutes the once popular view of spirit possession as modernity's other, characterized as primitive and backward. Instead, spirit possession cults are creative agents of change mediating between persons, regions, and even continents and between space and time. Interesting forms of symbiosis and rivalry exist with all major world religions. Pentecostal churches especially have become severe competitors in the last 20 years due to the popularity of the Holy Spirit and a very extensive media marketing (Meyer, 2006).

Conceptualizing Possession

Despite many attempts to define spirit possession (Howard and Mageo, 2006; Dawson, 2011a), the wide varieties of beliefs, religious traditions, and new inventions make it difficult to define what possession is and what it means for different people. The most conclusive is still Boddy's view that possession "is a broad term referring to an integration of spirit and matter, force or power and corporeal reality, in a cosmos where the boundaries between an individual and her environment are acknowledged to be permeable, flexibly drawn, or at least negotiable" (Boddy, 1994: p. 422). The relationship between spirits and humans has been accentuated further by Lambek as the trajectory of the spirit from "the ethereal into the material world" (2010: p. 28). In this act, the spirit offers his presence to his host as a form of "poiesis, as something being made, brought into being, and thereby also bearing on the world into which it is born" (ibid., 2010: p. 31). The myriad embodiments of spirits as ancestor spirits, former kings, or slaves as well as of specific ethnic or social groups, as guardians of the land or animals of the bush to name but a few underline their great variety. They are thought of as distinct personalities with special tastes for food, clothes, jewelry, technical equipment, colors, rhythms, and music which have to be provided by their hosts. The disclosure of the spirits' identity is dependent on different forms of communications, like dreams, images, voices, or eventually glossolalia but also through a sudden attack of illness or misfortune. These signs are interpreted as the spirits' calling which either lead to their exorcism or to their integration into the self of the afflicted person. These encounters are acted out in ritual performances in which spirits, mediums, and the public interact through the recitation of words, music, and dancing. Trance or ecstasy mark the very moment of transformation in which spirit and host fuse their identities. The identification with the spirit opens new horizons for the possessed who are situated in the global flows of present and past images.

Discourses on Possession

The fascination with the subject on the part of scholars has generated a large body of literature. Whereas in the nineteenth and the beginning of the twentieth century European case studies played an important role in discussions of spirit possession, processes of secularization shifted the scholarly interest in spirit possession onto non-Western societies. From the beginning, theories of spirit possession reflected the mainstream discussions in anthropology and were thus heavily influenced by changing theoretical paradigms. In recent years, the once dominant psychological and sociological approaches have been replaced by a hermeneutical interpretation of spirit possession.

Psychological and Sociological Approaches

An important issue in early studies was the truth or falseness in the experience of possession which de Heusch (1962) classified as authentic or inauthentic possession. As a consequence, psychological interpretations (Bourguignon, 1973) loomed large associating possession with multiple personalities and an altered state of consciousness. It was described as a form of pathology due to personal stress or social change.

Firth's (1964: p. 247) distinction between spirit possession and spirit mediumship opened a sociological path for new interpretations. He conceived spirit possession as a form of control by an external force of an individual whereas in spirit mediumship the spirit communicates through the medium with other people. Arguing from a functionalist point of view, Beattie and Middleton (1969) as well as Lewis (1989) elaborated on these differentiations. They were concerned with the social and political functions of spirit possession and its role in social change. Lewis' emphasis on gender inequalities which was *the* topic of the time inspired a vast amount of literature which, however, was extremely critical of his

 http://dx.doi.org/10.1016/B978-0-08-097086-8.12149-X

instrumentalist approach to spirit possession and his ignorance of its symbolic meanings as well as its theatrical dimension.

Hermeneutical Approaches

The sociological–functionalist approach was replaced by more sophisticated analyses which focused on the close link between possession, femininity, and the malleability of self. These studies concentrated on the opportunities for women and men to explore new identities, negotiate power relations between the sexes, and open up new spaces for social action through the deconstruction of male sexual hegemonies (Behrend and Luig, 1999: p. XVIIf). Boddy's (1989: p. 270) description of spirit possession as a 'metacommentary' was a benchmark since she drew attention to its counterhegemonic potential as well as its function as 'satirical allegory' (ibid.). The very ambivalence inherent in spirit possession ranging from subversion to confirmations of social order and traditional values was and is an ongoing discussion in the literature. Victor Turner (1967) had prepared the ground for such analyses by stressing the polysemic nature of symbols. The construction of symbolic worlds by mimetic ethnographies (Kramer, 1993) connected the past with the present. The spirits of powerful rulers, like the Sakalava kings in Madagascar (Sharp, 1999), displaced memory of slavery (see Wendel, 1999; Kenyon, 2011) or memory of the founder of the Kimbanguist church in a diasporic community in London (Garbin, 2011), are part of societies' cultural archives which are reinvigorated through performances of 'history from below' (Fabian, 1990) in spirit possession cults.

Such analyses are constitutive of the distancing gaze which is so characteristic of spirit possession performances. It was brought into near perfection by Jean Rouch' (1955) film about Hauka spirits which memorized and mocked the colonial past in Ghana. The possession with Hauka spirits opened an outer space for inner feelings which in everyday life had to be suppressed but were tolerated in spirit performances. Rouch's film initiated vehement discussions on ethnocentrism, on visual anthropology, but also on the relationship between spirit possession and colonialism (Stoller, 1995).

New Developments

During colonial times, many leaders of resistance movements were either spirit mediums or prophets, a tradition which was continued until the liberation wars of the 1980s in Southern and Eastern Africa (Behrend, 1999; Lan, 1985). Spirits were sometimes used for support and guidance by both sides during military confrontations like, for instance, between Renamo and Naprama fighters in Mozambique (Wilson, 1992). In African as well as Asian war-stricken societies, spirit mediums are also consulted to overcome the various consequences of war by retracing the whereabouts of missed bodies (Kwon, 2008; Perera, 2001) that were not given a proper burial out of political circumstances and are a constant threat for the living as long as the necessary rituals have not been performed. Spirit mediums, according to Perera, can also serve as an arena for negotiating feelings of aggression or revenge which are taboo in official Buddhism. They thus facilitate individual feelings of justice and alleviate processes of reconciliation which most states are unable to offer their citizens. They also give meanings to former inexplicable events and allow for the improvement of the karma of dead family members. Spirit mediums' compliance of these important social and political roles help to overcome what is called trauma or Post-traumatic stress disorder (PTSD) by medical doctors and psychologists.

The concept of trauma which is considered as a universally applicable medical category has come under severe attack (Kleinman and Desjaralais, 1996) because of its exclusion of different cultural and religious interpretations of pain. Kleinman and others shaped the sensitivity for contextual analysis for the attention of unequal power relations as well as the use of language and images when discussing 'social suffering' (Kleinman et al., 1997). In the same context, Laderman and Roseman (1996) demanded greater attentiveness toward music, dance, and rhetoric in the tradition of Stoller's work (1997) in Niger on the importance of the senses to understand the healing potential of spirit possession.

The fact that at present spirit possession takes central stage in the solution of conflicts be they related to war, to conditions of work (Ong, 1987), or other social problems led to a fundamental change in cult membership. Possession cults are no longer dominated by women, no more concentrated in rural areas, and are not even representative for the poor and downtrodden. The transcending of class boundaries is reported for several countries (Kapferer, 1991; Dawson, 2011b) and extremely common among members of Pentecostalism. But perhaps most striking is the revitalization of spirit possession in the megacities like London (Krause, 2008), New York (Brown, 1991), or Montreal (Drotbohm, 2008). Being exported by diaspora communities from the periphery to the center and vice versa, spirit possession cults are no longer confined to local places but have become nodes between several distinct worlds (Hüwelmeier and Krause, 2010). A case in point is the intensive exchange between spirit mediums in the Silicon Valley (US) and Vietnam (Fjelstad, 2010) in which commodities and therapies circulate with great intensity (Endres, 2010). Spirit mediums are thus able to create new cultural traditions, flourishing markets, and never-ending flows of ideas which are transported and embodied through traveling spirits.

Abstract

Spirituality and spiritual care is a growing field in the caring professions. This development has been led by nursing; social work has remained cautious and unsure of its role although the current emphasis on well-being is contributing to a change in attitude. Key to this has been the development of the concept of humanistic spirituality, which is distinguished from religion and argued to belong to everyone. Despite this, and the multiple spiritual care models available, spirituality and spiritual care have remained contested and problematized. An exciting development, progressed by social work, has emerged from challenges to the Western paradigm from indigenous spiritualities and ecospirituality perspectives.

Origins and Development

Spirituality studies are a burgeoning field in the literature of the caring professions and applied disciplines, which has emerged since the mid-1980s. Although a range of disciplines has contributed to its development as a dimension of professional practice – including social work, education, palliative medicine, business studies, and chaplaincy – it is nursing which is credited with raising the profile of spiritual care within secular health care systems (McSherry and Ross, 2012). This movement began in the Western developed world, where the primary thrust has been the distinguishing of spirituality from religion and, in consequence, the opening up of spiritual care as not only relevant for people of no religious persuasion, but also belonging to the remit of secular professionals and organizations. A parallel development has occurred in Asia, Africa, the Pacific Rim, and practitioners working with the indigenous peoples of Australia, New Zealand, and North America, where the language of spirituality has been utilized to reaffirm traditional, religious, and cultural values and practices that had been neglected in the widespread adoption of Western models of education and practice. This latter development has been led by social work, where it belongs to the drive for culturally competent practice (Coates et al., 2006), and business, where it is applied to a critical reappraisal of workplace ethics, values, and culture (Smith and Rayment, 2010).

The interest in spirituality and spiritual care among the caring professions should be understood in the context of broader societal developments. Sociologists of religion and other scholars have pointed to a number of apparently opposing trends: the decline in traditional religious adherence among white indigenous populations (Voas and Crockett, 2005); swelling church congregations (particularly RC and Pentecostal) in areas with high immigrant and migrant populations (Brierley, 2000); stable or growing Muslim communities (Office for National Statistics, 2011); and a growth in the popularity of 'New Age' religions and spiritual practices (Heelas and Woodhead, 2005). Davie has also suggested two trends that link practicing Christians with nonpracticing members of the local community – "believing without belonging" and "vicarious religion" (Davie, 2007) – both operating as the means by which people, who for the most part loosely define themselves as agnostic, maintain a tenuous connection with organized religion through use of its social functions, such as weddings, christenings, and funerals, and a largely nostalgic attachment to core beliefs and festivals, such as Christmas.

Some of the earliest writings about spirituality in the caring professions make explicit links with this pluralism of belief in the multicultural contexts in which they operate, as a significant imperative for a critical reappraisal of the neglect of a spiritual dimension in their practice (Lloyd [Holloway], 1997). Others start from a critique of the technicist, procedurally driven services that have been a feature of most health and social care systems in the developed world since the 1990s, and accompanying calls for a return to relationship-based practice, to point to the basis for that practice being in the profession's Judeo-Christian origins. For example, nursing texts, particularly the earliest spirituality literature, point to the beginnings of the profession in Christian caring institutions (McSherry and Ross, 2012); social work writers point to the heavy reliance on both Judeo-Christian thought (Bowpitt, 1998) and humanistic psychology in the development of social work's underpinning values and principles (Payne, 2011). However, such accounts are careful to distinguish contemporary spirituality practice from religious practice; the notion of 'spiritual but not religious,' introduced in the early literature, remains one of the most frequently used by the caring professions. Market surveys and opinion polls also confirm that spirituality is seen by many as, "a phenomenon independent of organised religion" (Nolan and Holloway, 2013: p. 161).

Concept and Definitions

Defining this broader, more diffuse 'spirituality' has been, and remains, a preoccupation. Definitions are premised on the assertion that a spiritual dimension is relevant for everyone, irrespective of whether or not they identify as followers of a religion. Despite the intense focus on defining what is meant by the term, there remains no universally accepted definition. Rather, within the multitude of definitions can be seen frequently repeated themes and aspects, put together in different contributions with varying emphases. For critics, the inability to agree a common definition highlights the fundamental weakness of the concept, but others point to the breadth and nuance contained in the attempts to define

spirituality as its strength. Early suggestions that the lack of a common definition inhibits the development of spiritual care have been overtaken by interest in its "practical relevance and application" (McSherry and Ross, 2012: p. 212). A core theme found in possibly every definition is the centrality of *meaning and purpose*. This is most usually coupled with a process such as the 'pursuit of meaning' or 'meaning making.' A second theme concerns *relatedness and connectedness* (Swinton, 2012). Less common, but an important strand, nonetheless, suggests a link with moral behavior and ethics (Holloway, 2012). These three strands are themselves interrelated. For example, it may be through relationships with others, and for some, a divine 'Other,' that individuals find their greatest sources of meaning; it may be through their behavior toward others that people are able to express the connectedness of their shared humanity; for some professionals, spirituality is the most fundamental connection they make with the people they care for and their work is the source of deepest meaning in their life (Sinclair et al., 2006). Canda and Furman (2010), whose work has been in the vanguard of articulating a spiritual dimension for social work practice, which they further describe as being at the 'heart' of social work, combine these ideas in a complex definition that describes spirituality as:

> … the wholeness of what it is to be human … The spiritual relates to the person's search for a sense of meaning and morally fulfilling relationships between oneself, other people, the encompassing universe, and the ontological ground of existence, whether a person understands this in terms which are theistic, atheistic, nontheistic, or any combination of these.
>
> Canda and Furman, 1999 (first edition): pp. 43–44. See also second edition (2010) p. 75

One argument made by social work writers is that there is considerable overlap between these core elements of spirituality and the core values and principles of social work:

> The cluster of values and world-views to which the concept of spirituality points us have been around far longer than social work, yet in very significant ways they have always belonged to the heart of social work.
>
> Holloway and Moss, 2010: p. 2

Alongside these core elements, however, is identification of the phenomenon of *transcendence*, which some writers, including from social work, include in their definition. For example, Lindsay adds to the search for meaning and purpose, "a moral dimension which reflects a concern with relationships to others, the universe, *and to some transcendent being or force* (my italics)" (Lindsay, 2002: pp. 31–32). Kellehear, a sociologist who writes about palliative care, sees the inclusion (implicit or explicit), or not, of transcendence in conceptualizations of spirituality as the key distinguishing factor (Kellehear, 2000). This is not a familiar term for social work and it is not used in the earlier spirituality literature emanating from the caring professions, although it is embedded in religious and New Age spirituality discourses. More recently, however, caring professionals have discussed transcendence in the sense of 'going beyond' the limitations of immediate circumstance and a wider context for the self. This is variously expressed as "transcending the ordinariness of everyday life" (Kellehear, 2000); being able to "transcend the situation such that it no longer has a problematic, painful or oppressive impact" (Holloway and Moss, 2010: p. 101); "grounding a person in their own centre and taking them beyond themselves" (Hegarty, 2007: p. 43).

Some writers choose to describe what might be termed the *attributes* of spirituality, rather than attempt a definition. Frequently highlighted are love, joy, compassion, caring, awe, wonder and mystery, beauty and creativity. van Hooft (2012) also notes that these are experienced 'in the presence of,' and contribute to, experiences of transcendence. Culliford helpfully explores how such 'feelings' are more than emotions but central to what he terms the 'psychology of spirituality':

> Consider the phrases, 'to be filled with awe', 'To be ecstatic with joy', 'To feel choked right up', 'To be paralysed with fear', and 'To be racked with tears'. What do they signify? They mean above all that the person is alive and responding at a profound and unpremeditated level to events beyond their control, beyond (at that instant) even the grasp of their intellect … these phrases describe strong emotions that often arise at life-changing moments.
>
> Culliford, 2011: p. 52

The search for a definition of spirituality goes on. In 2009, the US National Consensus Project on Palliative Care proposed the following as a 'consensus definition':

> Spirituality is the aspect of humanity that refers to the way individuals seek and express meaning and purpose and the way they experience their connectedness to the moment, to self, to others, to nature, and to the significant or sacred.
>
> Puchalski et al., 2009: p. 887

Recognizing that all definitions are to some extent culturally situated, Nolan et al. (2011) nevertheless propose a remarkably similar definition for the European context of palliative care. This suggests that the dominant articulations of contemporary spirituality in fact emanate from the Western paradigm of health and social care practice. Highlighting the themes that predominate in this literature, Holloway et al. (2011) summarize:

> Spirituality is more basic than religiousness. It is a subjective experience that exists both within and outside traditional religious systems. Spirituality relates to the way in which people understand and live their lives in view of their core beliefs and values and their perception of ultimate meaning. Spirituality includes the need to find satisfactory answers to ultimate questions about the meaning of life, illness and death It can be seen as comprising elements of meaning, purpose, and connection to a higher power or something greater than self.
>
> p. 18.

It is apparent that these understandings of contemporary spirituality are essentially *humanistic* (Elkins et al., 1988) and the term 'humanistic spirituality' is increasingly used. While the origins of humanistic spirituality can be seen in humanistic and transpersonal psychologies and allied to atheistic beliefs, it has

evolved in more recent practice as an umbrella and bridging concept within which traditional religious, secular, and New Age religious spiritualities can find common ground in the notion of common humanity (Nolan and Holloway, 2013). This makes it attractive to professionals working in multicultural contexts characterized by belief pluralism, seeking common meeting points to engage meaningfully with the individuals, families, and communities that use their services (Holloway, 2006). A humanistic spirituality that defines 'the spiritual' as concerned with the essence of being human (Swinton, 2007) and asserts this over functionalist and materialistic positions, sits well with professional discourses which privilege the inherent value and dignity of the person (van Otterloo et al., 2012).

Spiritual Care

It follows that for those who accept that spirituality applies to everyone, *spiritual care* is potentially relevant for every service user and belongs to the remit of every worker. However, health care workers in general and social workers in particular have shown reluctance and resistance to engage with spirituality (Holloway, 2007). Even for those practitioners who recognize spirituality as a potentially important dimension for service users and acknowledge its neglect in their practice, confusion and uncertainty is expressed about how to offer spiritual care and ambivalence as to its appropriateness within their role (Moss, 2012). Empirical studies find both health care professionals and social workers reporting that little or no attention was given to spirituality in their initial training (Furman et al., 2004), combined with constant calls to redress this deficit at all career levels (Yardley et al., 2009).

The importance of spiritual care in palliative and end-of-life care and bereavement is, however, recognized across the practice disciplines, including social work (Gwyther et al., 2005) and has generated the most research. Spiritual care research and models in this field have also used spirituality measures generated from other contexts. A systematic review of the English language literature from 2000 to 2010 on spiritual care at the end of life found, "a vast amount of documentation relating to spirituality, spiritual care and to end of life care" (Holloway et al., 2011: p. 8). After strict exclusion criteria were applied, 248 sources from 17 different countries (of which 24 were from social work and a further 4 interdisciplinary and social science making reference to social work) were examined in detail. This literature gives some clue to the reasons underlying the difficulties reported by practitioners. Importantly, it was noted that in the gray literature, there is a plethora of systems-level guidance which recommends that spiritual needs should be assessed and which describes the system for implementing this, but there is considerably less specificity about practice at the front line. Likewise, there is a growing tendency to include spiritual care in professional standards (see Society for Spirituality and Social Work, Arizona State University) but little educational research including evaluation of teaching and training programs (Holloway et al., 2011).

The most researched aspect of spiritual care is the assessment of spirituality, religiosity, and spiritual need or distress. The UK Department of Health review (Holloway et al., 2011) found continuing evidence that most health care practitioners do not undertake spiritual assessments, and of those that do, there is a wide variation in what that constitutes. A plethora of reasons is giving for failing to assess spiritual need: patient (*sic*) and/or family reluctance; fearing that they might cause distress; not knowing how to approach the subject; feeling embarrassed or awkward; regarding the subject as too personal; trusting that the chaplain or social worker will do it; having no belief themselves in God; the patient (*sic*) being unable to communicate; the patient (*sic*) being short-term; the worker not having enough time. However, while there is considerable resistance to formally undertaking a spiritual assessment, practitioners identified a number of ways in which they felt they were engaging with spiritual care. These included: 'being there'; supportive care – 'holding a safe nurturing space'; empathy and compassion – entering into 'weak places'; sharing the journey; sustaining. Thus, there is an implication that palliative care practitioners are happier with spiritual care perceived as *being* rather than *doing*. The social work literature, although comparatively sparse, generally works from the premise that a more active intervention is implied as a consequence of a heightened spiritual awareness and recognition of spiritual need. This will be discussed in the ensuing section.

Practice Models

Despite calls from practitioners for more training and practice guidance, there are vast numbers of models for spiritual care available – indeed, the array of models is often cited as a source of confusion. Rather less is known, however, about use of these models by practitioners or evaluation of their effectiveness. The research has generated a large number of assessment models but considerably fewer which might be termed spiritual care interventions. Social work is more inclined than other professions (such as nursing) to distinguish between assessment and intervention, which tend to conflate the two under the banner of 'spiritual care.' It is possible that this multiplicity of spiritual assessment models parallels a growing emphasis in all professions on assessment and is the natural first step in taking forward the growing interest in spirituality (Pesut and Sawatzky, 2006).

Assessment models can be categorized under four approaches: generic, quantitative, narrative (qualitative), and domain-based (Draper, 2012). Generic models ask broad open-ended questions about sources of meaning, support, and satisfaction within the person's life, which may lead to a focus on spirituality. Quantitative instruments use standardized and validated scales to 'measure' the degree of spirituality and religiosity of the individual, often within a broader dimension such as well-being. Narrative models provide a framework for exploring the person's 'story,' employing biographical and qualitative tools with an emphasis on the spiritual journey. Domain-based approaches explore spirituality as one domain of the person's life alongside the physical, emotional, and social domains, or alternatively focus on the spiritual dimension within every other domain. The greatest number of spiritual assessment models come from the US in the form of validated scales but these may not translate well to other societies and appear to have limited use as practice models

compared to their employment as research tools (Holloway et al., 2011).

Despite a significant concentration on spiritual need in the literature, there has been surprisingly little evaluation of the different approaches to spiritual assessment. What there is, debates the nature and ethos of the particular professional practice and how spiritual assessment fits into its overall approach to assessing problems and needs. Medicine and nursing recognize the importance of evidence-based practice and construe this as using validated quantitative tools, but construct arguments for incorporating other forms of spiritual assessment around epistemology and practice process (Draper, 2012). Thus, the type of knowledge that the clinician values in practice may be less likely to arise from facts that can be demonstrated empirically, than from processes which they have learned to trust:

> Modern nurses who understand their practice in terms of the 'nursing process' are therefore likely to assume that … the point of assessment is to identify patients' needs and to represent them in numbers … or words.
>
> Draper, 2012: p. 7

Social work writers have developed their ideas on spiritual assessment through focusing on the core values, skills, and approaches of the profession and the ways in which attention to spiritual issues and needs should be an embedded part. For example, there is a marked leaning toward holistic practice (Gilbert, 2011); narrative review (Hodge, 2005), empowerment, and partnership (Holloway, 2007); pursuing social justice (Holloway and Moss, 2010); change and transformation (Canda and Furman, 2010); relationship-based and humanistic practice (Payne, 2011); and critical practice (Gardner, 2011). Perhaps as a consequence of social work's long-standing reluctance to embrace quantitative measures, there is little engagement with the use of standardized scales and 'measurement' approaches. Moreover in keeping with its history as a 'problem-based' professional activity, the social work and spirituality discourse is rather more developed in relation to assessing and addressing spiritual need and distress than identifying service users' spiritual resources. The marked exception to this has been driven by mental health service users (including professionals who also identify as service users) who have insisted that their spirituality should be taken account of as a positive resource in their lives and not (as they frequently experience from psychiatrists) as a dimension to be ignored or vilified as the source of the problem (Coyte et al., 2007).

Spiritual care interventions fall broadly into two categories: integrated models, which embed spiritual care within a holistic framework of care; and spiritual care models, which take spiritual need as the starting point and may treat spiritual care as a discrete aspect (Holloway et al., 2011). A well-known example of integrated models is Sulmasy's biopsychosocial–spiritual model, based on the concept of 'whole person synergy' (Sulmasy, 2002). Sulmasy outlines a multidisciplinary care framework, based on the concept of dynamic interaction between the different aspects of a person's life. It fits with both domain approaches to spiritual assessment and the application of systems theory in social work interventions.

> according to this model, this spiritual state may … be modulated by the biopsychosocial state of the person, and the spiritual state may also modulate the biopsychosocial state
>
> p. 7

An example of a discrete spiritual care model, which is popular in the UK, is the Marie Curie Cancer Care spiritual and religious competencies that identifies four levels of competency and the tasks and functions required at this level as well as the palliative care professionals (and hospice volunteers) who should offer spiritual care at each level.

Contributions from Social Work

Generic social work theory has paid scant regard to spirituality, Payne's humanistic approach (2011), and Dominelli's global perspectives on antioppressive practice (Dominelli, 2010) providing notable exceptions. Likewise, social work's contribution to the spirituality literature has been relatively light compared to other professions of which nursing has produced the bulk of the material. Only a handful of practice models have been produced and they reflect the core concerns of social work in general. Canda and Furman (2010) build their framework for 'spiritually sensitive social work' on a foundation of six ethical principles incorporating commitment to the values of service, social justice, the dignity and worth of the person, the importance of human relationships, integrity, and competence. Gardner (2011) reflects these same values in her nine principles for 'critical spirituality practice,' adding to them a critically reflective dimension. Hodge favors a biographical approach to exploring with the person their spiritual and religious narrative; his "integrated framework" (Hodge, 2001) combines 'guided self-narrative' with an interpretive framework exploring six psycho-social-moral domains: affect, behavior, cognition, communion, conscience, and intuition. Holloway emphasizes partnership, building her Fellow Traveller Model of joining (spiritual awareness), listening (spiritual sensitivity), understanding (spiritual empathy), and interpreting (spiritual exploration) around the notion of companions on a spiritual journey (Holloway and Moss, 2010) and "maintaining the spirit" (Lloyd [Holloway], 1997). Moss's 'Why/Wow' model relates spiritual care to the tension in social work of engaging with both the light and the dark sides of human experience (Holloway and Moss, 2010). Chan et al. (2006) draw on eastern religions and philosophy to propose her 'body–mind–spirit' model for all social work practice. All acknowledge the dimension of cultural competence and spiritual practice competencies and standards are emerging, some as stand-alone and others incorporated into generic statements (Gwyther et al., 2005; Hodge, 2007). Furness and Gilligan (2010) emphasize that social workers should also be competent in addressing the significance of religious belief in the lives of many service users and detail a religious competencies framework. Mathews (2009) and Crisp (2010), while not proposing a model as such, take a life course approach to spiritual development, drawing on familiar social work concepts and tools. Similarly, spirituality as a component of quality of life and well-being (Harvey and Silverman, 2007),

the concept of resilience and a strengths perspective (Ungar, 2008), the language and approaches of restorative justice (Cheers et al., 2006), and the social worker as change agent (Canda and Furman, 2010) have been adopted by writers on spirituality and social work.

There is a thread which runs through these models proposed by social work and which is distinctive to them. This is the understanding that spiritual awareness and recognition of spiritual need are not of themselves enough; it falls within the profession's remit to respond directly to need and therefore all models detail the process of assessment and subsequent intervention, frequently through an interdisciplinary approach in which the social worker refers to and/or works alongside a religious or spiritual care professional. This is important in offering tools to address the concerns and inhibitions reported by practitioners (see earlier section). However, social work has made a more radical and significant contribution in its challenging of the Western paradigm, both in terms of the conceptualizing of spirituality and the model of spiritual practice. This contribution stems from the diverse voices of the global social work community. Social workers in societies where religion is a way of life and secularization is not the assumed default position have challenged the language of 'spiritual but not religious' as unhelpful and meaningless (Wong and Vinsky, 2009). Social workers belonging to and/or working with the indigenous peoples of North America, Australia, and New Zealand have drawn on insights from a spiritual tradition that understands the relationship between human beings and their environments as sacred and which therefore implies a wholly different set of priorities and starting points for social work interventions (Coates, 2007). Social workers from Asia have challenged the individualism inherent in the contemporary personalized and internalized spirituality discourse, endorsing an alternative world view based on communitarian values and responsibility to others (Yip, 2005). Thus ecospirituality models (Nolan and Holloway, 2013) that enrich understanding of the connections between place, identity, and well-being have much to offer to the emerging interest in care environments and aging and dying 'in place.' Equally, the privileging of connectedness and relationship offers an important corrective to therapeutic models which emphasize individual self-actualization to the neglect of social context and nurturing of social capital. These perspectives are leading a potentially significant evolution of the original conceptualizations of spirituality and understandings of spiritual care in the caring professions, although their adoption outside of social work is as yet limited.

This insistence that valuing diversity and challenging social inequality and oppression is core to "spiritual practice" (Coates, 2007) is a theme possibly unique to the social work and spirituality literature, which at the same time recognizes that religious and spiritual traditions can be equally oppressive (Furness and Gilligan, 2010). Indeed, anecdotal evidence would suggest that both witnessing and experiencing religious cultures as oppressive, particularly toward certain groups such as women and nonheterosexuals, lies behind much of the (historical) antipathy in social work to inclusion of spirituality in their practice. This is approached on an individual therapeutic level through the exploration of harmful spiritual narratives and the cocreation of a new empowering narrative (Hodge, 2001, 2005). At the social structural level, writers draw on liberation spiritualities and theology to argue that spiritual practice unites individual, social, and political concerns (Holloway, 2007). Understanding spiritual concerns as well as spiritual and material resources as integral to community development is, according to Chile and Simpson, "the fire of social justice which brings about radical transformation of structures of society" (Chile and Simpson, 2004: p. 322). Gardner (2011) offers critical social theory as the means by which both sides of the spirituality empowerment-oppression see-saw may be held in balance, reminding that, "there are certain values we would want to affirm across spiritual and religious boundaries as well as values we wouldn't" (p. 48). The key to critical spiritual practice is thus making explicit the dynamics of power in whatever direction they are operating. This chimes with arguments from mental health service users that for too long their spirituality has been seen by psychiatrists as part of their problem, rather than as they experience it, a resource which helps them to make sense of their illness (Coyte et al., 2007). A growing band of psychiatrists, many coming from the transpersonal psychology tradition, support this position, utilizing spiritual perspectives in a person-centered approach to their practice (Culliford, 2011).

Split Brains and Human Consciousness

Colwyn Trevarthen, The University of Edinburgh, Edinburgh, UK

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Research on the consequences of complete section of the forebrain commissures in cats and monkeys, and in human patients operated to control epilepsy, has clarified how the brain mediates perception, learning, memory, and the control of movements, and has raised many questions. No single process of consciousness and no simple localization of 'modules' of perception or reasoning have been found. However, consistent differences between the awareness of the left and right hemispheres in human beings, and regarding their capacity to integrate experience of objects with skilled action, to employ language in speech or writing, to imagine contexts for discrimination and decision making, to attribute qualia to objects, and to sympathize with the motives and feelings of other persons, cast light on how the human brain is uniquely adapted for cooperative cultural life. The findings of split brain research have importance for the whole range of scholarship that attempts to explain the human condition.

A History of Split-Brain Research

A 'split brain,' usually the brain of a mammal, is one in which all direct, 'one-neuron' connections between the two forebrain cerebral cortices have been cut. The largest interhemispheric bridge, or commissure, is the corpus callosum (Bogen, 1985; Innocenti, 1986) (see **Figure 1**). The first split-brain operation was performed on a cat in 1952, combining commissurotomy (sectioning of the corpus callosum and anterior commissure) with division of visual crossover fibers, the optic chiasm, at the base of the brain. Split-brain cats see and learn with each eye connected to a different hemisphere. Transfer of visual learning between the hemispheres is abolished (Myers and Sperry, 1953). In monkeys, commissurotomy separates two eye–hand coordination and learning systems, each hemisphere having predominant cortico-motorneuronal control for limb movements on the other side of the body and within the visual half field on that side (Sperry, 1961). An intention to move one hand determines which cortical visual system will perceive and learn (Trevarthen, 1962, 1965, 1974a, 1987). Perception around the body in the periphery of the visual field, including 'ambient' preattentive awareness of space and motion properties of objects, is not divided in the split brain, indicating that subhemispheric (brain stem) systems, which remain unified, can integrate core perceptuo-motor functions directed to the 'behavior space' surrounding the body (Trevarthen and Sperry, 1973; Trevarthen, 1987).

In the 1960s, Los Angeles neurologists and neurosurgeons Bogen et al. (1965), encouraged by the integrated functional state of split-brain animals, performed commissurotomy operations on human patients to control life-threatening epilepsy, with excellent results. Psychological tests of these patients, under the direction of Roger Sperry at the California Institute of Technology, demonstrated a divided consciousness and two different cognitive systems for focal conscious awareness and skilled movements (Sperry et al., 1969). Only one, in the left hemisphere, had normal control of speech, and it was superior in logical or 'propositional' thinking. Right-hemisphere consciousness understood language at a simple level, and it was superior in awareness of relationships and configurations of experience called 'appositional' (Bogen, 1969). Roger Sperry (1982), who initiated split-brain research in animals and supervised the tests of awareness in humans after commissurotomy, received

Figure 1 Anatomy of the cerebral commissures. Sagittal sections of the brains of cat, monkey (rhesus macaque), and human adult, showing the corpus callosum (c), anterior commissure (a), and optic chiasm (oc). The estimated numbers of nerve axons in the corpus callosum of each species are indicated. This illustrates the enormous expansion of cortical functions in human beings, and their bilateral integration through the corpus callosum.

a Nobel Prize for this work in 1981 (Sperry, 1982). Split-brain research has been enormously influential, clarifying intrinsic functions of consciousness in the brain, and the cerebral symmetry of human motives or cognitive strategies that guide different purposes in action. However, the experimental tests performed with individual subjects, concentrating on the visual sense, touch perception of objects by the hands, cognitive abilities for identifying objects, and especially language and rational skills, have led to restricted views. They do not relate the functions of consciousness to their meaning for active, imaginative, and emotion-charged life in the world at large, in human relationships, and in the social and cultural world. Now, with the aid of functional brain imaging of normal subjects engaged in a wider range of tasks, and with information from infancy research on the innate capacities of the uneducated human brain for sharing experience, a new interpretation of the effects of commissurotomy in humans, acknowledging the asymmetric substrates of motivation and attention in subhemispheric systems, is required. It will need to incorporate scientific understanding of how advanced mammalian brains organize motives and emotions to engage with and evaluate the physical environment with intelligent prospective consciousness, how they learn concepts and representations, and how they may collaborate by communicating their intentions, experiences, and affections by expressive body movements.

Perception, Learning, and Prospective Control of Movements

Before the 1940s, the functions of the corpus callosum, estimated to have about 1000 million axons, were unknown (Akelaitis, 1944). Early in the 1950s, Sperry at the University of Chicago, who was researching the anatomy of visual form perception in the cerebral cortex, proposed a surgical investigation that was to yield new insights into the brain systems of consciousness (Evarts, 1990: pp. xix–xxi). Ronald Myers, a research student with Sperry, demonstrated that a cat's visual experience was divided in two by cutting the corpus callosum, and proved that such experience could be transferred by the callosum between the hemispheres (Myers and Sperry, 1953).

In the 1950s and 1960s, Sperry's research group, now at the California Institute of Technology (Caltech), exploited what was now called the 'split brain' to study visual and tactile perceptions, memories, and motor control in cats or monkeys (Sperry, 1961). Studies with monkeys showed that, while ordinary pattern discrimination was completely split, less 'figurative' or focal visual experiences were not completely duplicated after split-brain surgery. They also proved the importance of 'motor sets' or 'intentions to move' that 'anticipate' sensory information for the whole body, and that invoke undivided systems of the brain stem and cerebellum. They confirmed an approach to conscious perception of objects not only as the processing of an input of information from the distance senses for identifying and manipulating objects, and for remembering them, but also as goals for coordinated movement, which must both anticipate consequences within the body, proprioceptively, and regulate the serial ordering of movements in hopeful projects of engagement of a coherent Self with the external world (Sherrington, 1906; Lashley, 1951; Sperry, 1952; Bernstein, 1967; Maturana and Varela, 1980) and then in companionship with other Self-aware subjects (Maturana and Varela, 1992; Bråten, 2009; Malloch and Trevarthen, 2009; Gallese, 2012).

In 1962, the effects of commissurotomy, undertaken to arrest life-threatening epilepsy, were investigated in a human patient (Bogen, 1985). Sperry directed psychological tests of consciousness, learning, and various skills after the operation (Sperry, 1968). Commissurotomy to treat multifocal epilepsy in other patients made it possible to replicate tests of rational consciousness in the left and right hemispheres; their similarities and differences; their convergent influence over the acts, ideas, and feelings of the whole person; and the role of language (Sperry, 1968, 1974, 1982; Sperry et al., 1969).

Commissurotomy research confirmed Sperry's theory of the causal potency of motor intentions (Sperry, 1952), and encouraged him to develop a theory of self-consistent conscious ideas and beliefs, and moral impulses (Sperry, 1977, 1983). It stimulated the neuropsychological analysis of hemispheric differences unique to humans, and, by clarifying the special modes of processing in cortical territories, supported the 'cognitive revolution' of the 1960s (Sperry, 1993).

Since the classical period of split-brain research in the 1960s and 1970s, interest in hemispheric differences has flourished, and the cognitive processes, language processes, and memory of commissurotomy patients have been studied in new, detailed ways. The effects of the operation on visual awareness, visual attention, and capacity to use language or make interpretations of configurations of items in the visual world have been fully confirmed (Holtzman et al., 1984; Benson and Zaidel, 1985; Nebes, 1990; Trevarthen, 1990; Corballis, 1991; Gazzaniga, 1995). Although commissurotomy was highly effective in limiting seizures, the operation carries risks, and, with improved means of controlling epilepsy, it is now rarely performed.

Split-Brain Experiments and Intelligent Movements of Cats and Monkeys

Myers applied the stereo-microscope surgery developed by Sperry to cut the crossover of visual nerves in the optic chiasm under a cat's brain, so each eye would lead to only one cerebral hemisphere (**Figures 1** and **2**). In 1953, he and Sperry reported the transfer of visual memory between the hemispheres in cats with the chiasm divided, and the abolition of this transfer when the corpus callosum was cut (Myers and Sperry, 1953). Outside carefully controlled test situations, the animals moved normally.

Monkeys also experience independent visual perception and memory in the two brain halves after the optic chiasm and forebrain commissures (corpus callosum and anterior commissure) are cut (**Figure 1**). Again, the operated animals retained normal coordination of movements and attention when free to orient, correcting for loss of awareness due to the surgery. Split-brain monkeys learn two, mutually contradictory,

Figure 2 Human brain showing asymmetric functions in the cerebral hemispheres. The hemispheres are separated after commissurotomy (the 'split-brain' operation). Above: the two hands in the visual field, with the subject's attention fixated on the tip of the paintbrush. L = left half of visual field; R = right half of visual field; oc = optic chiasm.

visual discrimination habits in the right and left half-brains, showing that they possess double and separate realms of consciousness (Trevarthen, 1962; Sperry, 1977). In the cat, each disconnected hemisphere directed movements of the whole body, but with monkeys, a hand on the same side as one seeing hemisphere was, at least in the immediate postsurgical period, less willing to respond and, if forced into action, was clumsy, as if blind. Crossed pathways linking each cortex to the opposite hand were superior for guiding fine, purposeful movements of the fingers. Related split-brain projects demonstrated shifts of attention between the two separated halves of the cortex and the effects of preparatory sets to move in particular ways. The results revealed the global design of the mammalian brain for awareness, learning, and voluntary action, and the special adaptations for conscious control of the hands of primates (Sperry, 1961; Berlucchi, 1990).

What a chiasm–callosum sectioned (split-brain) monkey sees and remembers (i.e., in which hemisphere visual perception and learning occur when both hemispheres are presented stimuli) depends on which hand the animal chooses for response. This is evidence that intention can instruct experience and that activities of the neocortex are directed intrinsically by purposeful impulses generated in the brain as a whole, not just by processing the input of stimulus information at the cortical level (Trevarthen, 1987).

When a monkey learns a complex two-handed skill, the memory of how to move is located more in the hemisphere opposite the dominant hand (i.e., the hand that the individual spontaneously prefers to use for fine, consciously regulated manipulations) (Trevarthen, 1978a). A split-brain monkey's visual awareness can be turned on or off in one side of the brain by changing which hand the animal uses to manipulate the test apparatus to gain a reward. When using the right hand, the monkey becomes conscious on the left side of its cerebrum and is unable to see with the right cortex. This causes the monkey to be inattentive to things in the left half of its experience, and makes it likely to imagine things that did not exist there. This clarifies 'perceptual neglect' and 'illusory completion,' phenomena known from clinical neuropsychological research with consciousness of patients who have lost function in parts of their cerebral cortex.

Tests of vision in the divided brain led to the theory that the sensory systems are linked to a hierarchy of motor coordinative systems, which either gear body movements to the layout of the surrounding world, or direct the subject to select objects that have life-relevant qualities (Trevarthen, 1978b). Two active visual systems were distinguished: wide-field and part-conscious *ambient vision* informs whole-body locomotion and orientation; and *focal vision*, which employs the foveae to see within only a few degrees of visual angle and with precise intermittent fixation of gaze, inspects detail and identifies objects (Trevarthen, 1968, 1974a, 1987). The former, involving many subcortical centers as well as parts of the parietal cerebral cortex, acts as motivator and map reader for attention in the latter, which involves more conscious vision

of shapes, colors, and patterns. The split-brain operation divides focal vision because its essential processes are confined to the cortex, but it leaves ambient vision largely intact.

Human Commissurotomy Patients and the Cultural Mind

In 1960, Joseph Bogen, a Los Angeles neurosurgeon, saw a patient who was having progressive, life-threatening seizures as a result of head injuries sustained as a paratrooper. In the light of research with monkeys that showed that commissurotomy could leave essentially normal control of whole-body action and the distribution of awareness, it was decided that cutting the corpus callosum and other interhemispheric commissures, 'total commissurotomy,' would reduce the epilepsy. This operation was carried out in 1962, and the epilepsy improved significantly. Sperry and Bogen, with Michael Gazzaniga as research assistant, began systematic psychological tests at Caltech on the effects on perception, speech, and motor control. Instead of relying on standard neurological procedures, original tests were devised based on principles learned from split-brain animals (Sperry, 1968, 1974; Sperry et al., 1969). The first report, with clinical observations made by Bogen, described the resultant left-right division of human consciousness (Gazzaniga et al., 1962). Norman Geschwind and Edith Kaplan, in Boston, described comparable 'deconnection' phenomena in patients with lesions that interrupted cortico-cortical links (Geschwind and Kaplan, 1962). The main hemispheric differences revealed by the early work at Caltech with commissurotomy patients are summarized in Sperry's Nobel address (Sperry, 1982).

Tests confirmed that awareness of objects, either seen by half of the brain (in the left and right halves of the visual field) or felt in the left or right hand, was essentially normal, but, as in the earlier animal studies, when free orientation was prevented, the left and right mental realms were as separate as if in separate heads (**Figure 2**). Only when the subject shifted visual fixation or passed an object from one hand to the other did the one hemisphere know what the other perceived. As with the monkeys, human commissurotomy subjects experienced unified *ambient* visual functions but split *focal* vision (Trevarthen and Sperry, 1973; Trevarthen, 1990, 2004). This difference in functional level of control, defined by the motor activities of the subject in selective engagement with objects in the world, is of fundamental significance for interpretations of the meaning and value of knowledge gained by research on commissurotomy patients (see **Figure 2**).

Although both hemispheres of a commissurotomy patient proved to be conscious in all modalities of sense, only the left could speak or write. Surprisingly, however, given that left-hemisphere lesions can produce total aphasia, the right hemisphere, although speechless, could nevertheless comprehend speech (Gazzaniga and Sperry, 1967; Zaidel, 1990; Trevarthen, 2004). It picked up information quickly from utterances made by the left half-brain, could read common words flashed to the left visual field, and could follow verbal instructions. It was, however, conspicuously weak at calculating and in comprehending logical propositions. Jerre Levy, taking a lead from differences revealed by tests of intelligence, showed that in the nonspeaking right hemisphere, classically referred to as the 'minor' hemisphere, mental faculties that imagine spatial relations and transformations in space were more highly developed than in the left 'dominant' side of the brain. Thus, two different, complementary kinds of cognitive strategy, two kinds of consciousness, were demonstrated (Levi-Agresti and Sperry, 1968; **Figure 2**).

The surgically separated left hemisphere commands fluent speech and can generate and retain phonological images of speech sounds. It performs serial logical propositions such as are expressed in spoken, gestural, or written language, and it is adept at the kind of combinatorial and systematic logic that is required for formal mathematics employing symbols or score-based musical thought by skilled performers. The right hemisphere, in contrast, has superior mastery of the immediate 'appositional' experience (Bogen, 1969) – of forms perceived by sight, sound, or touch – and, according to recent research, of odors, which are detected and evaluated emotionally by the right nostril (which projects to the right hemisphere) but named by the left (Herz et al., 1999). The right hemisphere can remember affect-laden experiences such as these better, can distinguish and remember faces better, and has richer reactions to colors and to affective tones of the voice in song or speech and its prosodic quality or 'musicality' (Panksepp and Trevarthen, 2009; Turner and Ioannides, 2009). It perceives more easily resemblances in topological but not Euclidean geometry. Commissurotomy patients have a color anomia, an inability to name colors, because the disconnected right hemisphere has a superior but inarticulate ability to perceive and evaluate color (Levy and Trevarthen, 1981). There is evidence that an undivided brain-stem color vision defines a dichromatic distinction between blue space and the reddish-brown solids, part of the natural layering of the conscious mind to serve different forms of action in the world (Trevarthen and Sperry, 1973).

Each hemisphere separated from its partner by section of the corpus callosum can orient attention to left or right, and can experience illusions of experience in the ipsilateral field that has no clear vision, enabling perceptual completion, which is dependent on a relaxed motor state (Trevarthen, 1974a; Levy et al., 1972; Trevarthen, 1987, 2004). Jerre Levy and Colwyn Trevarthen used 'stimulus chimeras,' which are pictures showing different half objects on either side of the midline, to observe biases in cognitive activities of the hemispheres induced by what a commissurotomy patient intended to do, or by what he or she had been told to think about (Levy and Trevarthen, 1976). They called the motive sets that were capable of turning on or off one or other hemispheric cognitive mechanisms, sometimes independently of the different cognitive aptitudes on the two sides, 'metacontrol.' Similar habitual arousal biases in normal subjects may underlie individual differences in cognitive aptitudes and personalities. They indicate characteristics involving the core motivating mechanisms of the Self mediated by subcortical and brainstem integrative systems (Northoff and Panksepp, 2008), which have asymmetries derived from complementary 'ergotropic' and 'trophotropic' regulations of the autonomic system, concerned, respectively, with assertive action on the environment and with self-sustaining nurturance of vital

functions of the body (Hess, 1954; Trevarthen, 1996). Emotional asymmetries have received little attention in research with split-brain subjects.

Theoretical and Philosophical Implications and Problems: Seeking a Wider Scope for Enquiry

Iain McGilchrist (2009) presents a comprehensive review of evidence from neuropsychology, phenomenological psychology, and cross-cultural studies that the right hemisphere is adapted for vigilance, sustained alertness, and the emotional intensity of experience for novel events, while the left chooses and pays focused attention to elements, seeking recognition of what is known for rapid action. These complementary modes of awareness and attention to experience involve different motor activities and support different skills, for the individual and in communication. Both of the hemispheric modes of awareness are required for the mastery of cultural experience, and for the individual to become a contributor to elaborate and sophisticated life in society with its different employments.

Michael Gazzaniga has given special importance to the top-down 'interpretations' of focal interests and their sequencing in the left hemisphere. He concludes that human left-hemisphere intelligence, with language, overcomes the limited, more primitive, animal awareness of the right hemisphere by giving learned rational interpretations, in symbolic form, to what is perceived (Gazzaniga, 1985, 1998). This theory of human consciousness, privileging language, neglects the role of intuitive, implicit, emotional, and intersubjective contexts for the development of discriminating and rationalized awareness, and the importance of creative thinking for the capacity to imagine a less focused, wholistic view of elements in their context, and to imbue them with feeling (Bogen, 1997; Bogen and Bogen, 1969; Panksepp, 1998, 2005; McGilchrist, 2009). All of human cultural cooperation and production depend on intimate communication of this more passionate motivation, besides systematic rationality and its codification in symbols (Trevarthen, 2012). The lexicon of language is learned with awareness of whole-body expression and the intrinsic asymmetry of manual gesture (McNeill, 2000). If single subjects are required to make precise identification and naming of different forms of objects, with rational inferences to explain them, then the left-hemisphere abilities have an advantage. The special requirements of mutual, intersubjective intelligence, and how they may be mediated by special intentional and emotional capacities for shared experience that are constitutional in the human brain (Gallese, 2012), are not revealed.

Tests with commissurotomy patients support findings with brain-damaged and normal subjects showing the right half of the brain to be involved in emotional communication and the mediation of direct social interactions (McGilchrist, 2009). The development of asymmetry of behaviors in infancy, and the asymmetry of motives and emotions supporting maternal affection and care for young children, gives evidence that differences of function in disconnected hemispheres in adult humans arise from inherent differences in the motives and emotions of the left and right sides of the brain (Schore, 2000, 2012; Narvaez et al., 2012). Anatomical differences in the fetal body and brain (Trevarthen, 1974b, 1985, 1996, 2001) and fetal hearing of the mother's heartbeat and preferential recognition of her voice by the right hemisphere (DeCasper and Prescott, 2009) confirm that both emotional differences and predispositions for different learning abilities are established by morphogenesis. They form as systems that will play a part at all stages of the learning of language and cooperative skills (Trevarthen and Delafield-Butt, 2013).

Commissurotomy research has stimulated neuropsychological investigation of the effects of unilateral brain injury; tests of normal perceptual, cognitive, and motoric asymmetries; and research on the anatomical asymmetries of the cerebral cortex. The findings have been invoked to explain why children with similar opportunities for learning may be different in educational performance, and why adults show different intellectual aptitudes and job preferences. It is likely that hemispheric biases in cognition and intellectual differences between adults are both consequences of inherent styles in purposes and emotions, and of different experiences and opportunities for practice and for communication with others. There is good reason to believe that, for a species that depends upon sharing of elaborate cultural knowledge and skills that require many complementary talents and inclinations, the development of the brain relies upon both genetic and epigenetic production of individual differences, such as is evident in the variety of physical appearance; of skin color, hair, eyes, and facial configuration; and of manners of moving and voice, which are so evident in humans. In addition, the brains of modern humans are particularly susceptible to modifications by cultural experience and artistry, which enhance individualities (Han and Northoff, 2008; Trevarthen, 2012).

In the normal brain of an individual, the hemispheres work in tight partnership. The intuitive response to experience and the evocation of imagery linked to phenomenal reality by metaphor, on the one hand, and verbal analysis and prescription of esthetic judgments, on the other, are two natural brain systems that develop as complements in the making and communicating of language, technology, and art.

Findings with commissurotomy patients have been used to support theories of 'modular intelligence' derived from the neuropsychological and cognitive science fields, and attempts have been made to apply these theories to evolutionary changes in hominid behavior and the different kinds of cognitive processing that are inferred. However, such models of the mind are incomplete if they do not incorporate explanations of the motivations that generate both action and awareness, and the communicable emotions that evaluate them (Trevarthen, 2004). The skills, concepts, and memories of language are stored over wide areas. Parallel-distributed processes contribute to the comprehension of language, as for facial recognition, spatial awareness, and categorical understanding of objects, or for executive planning and motor sequencing. The development of the cortical elements and assemblies involved in all of these functions depends on associative cortico-cortical links, both within each hemisphere and through the corpus callosum. These supplement equally massive connections to and from cell populations beneath the cortex, which integrate intentional

self-awareness and give emotional appraisal to the expected consequences of agency (Panksepp and Panksepp, 2000). The human subcortex is capable of integrating a conscious motivation of movements of the whole body, including the expression of socially responsive emotions even in the absence of the neocortex (Merker, 2007).

A majority of humans are 'right-handed' and have been since Neolithic times, preferring to take conscious control in the right hand, especially for communicating by gesture, carefully directing implements, and finishing the details of their fabrication. About 15% prefer the left hand. Most of us tend to move the right half of our mouths more, or earlier, in speaking, and look right as we speak. These skills, elaborated by learning, originate in asymmetries implanted in subcortical systems before birth (Trevarthen, 1996).

It has been clear for more than 100 years that talk, and especially the perception and execution of the rapid articulations of mature speech, is more strongly represented in the left hemisphere. There is now evidence that the learned performative skills of singing and instrumental music have the same laterality to the left hemisphere as skilled speech, but the affective qualities of music are more strongly appreciated in the right hemisphere (Turner and Ioannides, 2009). Right-hemisphere lesions selectively impair object and event recognition by sight or hearing and may have devastating effects on the capacity to recognize who another person is and what their emotion may be. Right-posterior lesions can also weaken a person's discrimination of his or her own expression of feeling, and lower self-awareness generally. The cognitive and performance functions of the right half of the brain are clearly important to a person's cultural life in a community, and to the acquisition of many skills that language may find hard to describe, and they serve to support language-mediating functions in the left hemisphere.

One important defect of awareness found in commissurotomy patients, contrasting with the overall normality of their behaviors and experiences when free to orient their actions, is alexithymia, a difficulty in identifying and describing feelings (TenHouten et al., 1986). It appears to be a straightforward consequence of dissociation between the left hemisphere's abilities to identify and describe experiences and the right hemisphere's immediate affective response to a moving event. This dissociation interferes with the function of the corpus callosum to mediate between creative imagination and factual specification, which goes beyond the function of transferring perceptions and memories (Bogen and Bogen, 1983). Dahlia Zaidel found that disconnection of complementary aspects of experience also interferes with the formation of new memories following the separation of the hemispheres (Zaidel, 1990).

There has been much speculation about how recurring asymmetries in works of art might be related to the anatomy of the brain, and our common brain asymmetry does appear to have been unknowingly exploited by many painters to generate esthetic effects (Gardner, 1982; Levy, 1988; Trevarthen, 1995). There is a school of art teachers who draw on split-brain research to guide pupils to make stronger use of the right hemisphere, claiming that this generates more dynamic, coherent, and aesthetically pleasing forms, and some require right handers to sketch unthinkingly with their left hands (Edwards, 1979). We have to learn how to talk about what is beautiful in art, and it is inherently difficult to recall what we say. Language offers a powerful tool for introspecting, for planning actions, and for manipulating information in 'phenomenal absence' from its source (i.e., in memory), but the lexicon of speech is limited for representation of the quality of imagination, and it seeks aid from expressive gesture, intonation, and metaphor. Musical communication, which is universal among humans, serves to express affective relations and to establish a sense of belonging to a community of vital agents who share emotional appraisals of companionship in experience, from infancy (Malloch and Trevarthen, 2009).

Sperry's work with commissurotomy patients convinced him that coherent, Self-related brain-generated awareness and evaluation have a determining role over the experience obtained by learning. He concluded that science has to give consciousness an interactive, causal role in brain function. Subjective mental states explain conscious behavior and its changes, and they determine what a person is and does. This view gives the higher 'macro,' mental, vital, and social forces equal importance in scientific explanations of life, such as in physics and chemistry. However, it is a conception of consciousness as a top-down process, and there are good grounds for taking a rather different view that sees consciousness as a product of the emotions that constitute awareness of a 'core self,' mediated from the brain stem, below the elaborations of memory in the cerebral cortex (McGilchrist, 2009: pp. 220, 221). Sperry's thinking about human consciousness acknowledges the importance of values and emotion, as is summarized in the *Nobel Prize Conversations* (Sperry et al., 1985).

Abstract

Although traditionally inclined to view sport as an insubstantial topic for investigation, anthropologists have in recent decades devoted increasing attention to the powerful attractions of games, sports, and embodied athletic practices, along with their effects within social life. Working within and beyond conventional sociological definitions of sport, anthropologists have applied ethnographic and comparative methods to good effect. Treating sport as embodied social practice that hinges around its playfulness and celebratory capacities, they are examining its varied meanings and uses, which range from the formulation of individual and cultural identities to the facilitation of domestic, economic, and state purposes.

The Anthropology of Sport

The positioning of anthropology in the nineteenth century as the science of the nonmodern and 'primitive' drew its practitioners away from the study of athletic games and contests, not least because recently codified Western sports were being proclaimed as exemplars of modernity (Archetti, 1998b). But the ensuing anthropological neglect of sport and sportlike activities was never absolute. Several early ethnographers and ethnologists crafted detailed descriptions of Native American games (e.g., Mooney, 1890; Culin, 1907). For the most part, however, games and athletic competitions that anthropologists stumbled across while conducting field research tended to be noted sporadically, if at all, and regarded as incidental to more definitively 'indigenous' social and cultural customs. Only occasionally did individual anthropologists (e.g., Firth, 1930; Fox, 1961) make a game or sport a focal part of an ethnographic report.

This pattern began to alter in the later decades of the twentieth century as part of a more general rethinking of the objectives and practices of sociocultural anthropology triggered by a rising tide of processual and performance-oriented theoretical approaches. This prompted, among other things, an easing of the inclination to rate games and sports as ephemeral and inconsequential pastimes. In rapid order there appeared a seminal essay on the Balinese cockfight (Geertz, 1972), an ethnographic film on Trobriand cricket as an 'ingenious response to colonialism' (Leach, 1976), and a monograph that traced the dynamics of Afghan political leadership through the equine sport of *buzkashi* (Azoy, 1982). These and other accounts raised novel ethnographic and analytic possibilities by looking into games and sporting activities played by peoples living in places that had figured prominently within the disciplinary literature. The sport practices and passions of persons and groups recounted in such works could not readily be dismissed as falling outside the bounds of anthropology.

Studies focusing upon the ritual forms, social relationships, cultural symbols, and performative identities generated through games or sports of various types also began to be mounted beyond the boundaries of traditional anthropological locales. For instance, essays about baseball in the United States (Gmelch, 1972), American football (Arens, 1975; Dundes, 1978), and wrestling in small-town Ontario (Freedman, 1983) guided anthropological readers into less usual ethnographic settings, as did MacAloon's pioneering study of the modern Olympic games (1981). These and other works cumulatively placed the investigation of sports, athletic competitions, indigenous games, and comparable forms of embodied practice within the ambit, if not necessarily at the center, of anthropological endeavor. By the end of the twentieth century, anthropologists had published analyses of, for example, traditional forms of wrestling (Alter, 1992) and cricket (Appadurai, 1995) in India, the rise of modern sports in post-Maoist China (Brownell, 1995), baseball in the Dominican Republic (Klein, 1991), capoeira in Brazil (Lewis, 1992), bodybuilding in the United States (Klein, 1993), the 1994 Winter Olympic games in Norway (Klausen, 1999a), and football, polo, and tango in Argentina (Archetti, 1999a). The capacities of sport to engage players and spectators as well as to mobilize involvement by sport organizers, politicians, and entrepreneurs featured in some anthropological conference papers and publications. What remained to be seen was whether the study of sport would progress beyond the status of a permissible niche enthusiasm to become a more widely read and revealing branch of inquiry within the discipline.

Anthropologists come to the study of sport by various routes. Taking cognizance of a sport played or an embodied practice conducted within a certain setting might be an unexpected outcome of examining other matters, as was the case in Manning's ethnographic encounter with cricket in the course of mapping the articulation between politics and festivals in the Caribbean (Manning, 1981). Delineating the attributes of a game or embodied practice might be driven by ethnographic curiosity as much as by an interest in sport per se. Reporting these findings in a subsequent publication might complete a one-off encounter with sport for one anthropologist or mark a more fundamental reorientation of intellectual interests for another. Either way, anthropologists whose attention is drawn to the study of a sport or sportlike practice must choose whether to conduct their inquiries primarily within the rubric of anthropology, locate these within the burgeoning interdisciplinary field of sport studies, or, seek to straddle, if not necessarily reconcile, these fields of study.

An underlying consideration in such decisions involves the contested manner in which sport has been envisioned and defined by scholars. Historians and sociologists have largely

tended to reserve the term 'sport' to refer to athletic games and practices formalized in Western industrial societies during the nineteenth and twentieth centuries. Thus, Guttmann's (1978) rendering of modern sports characterized these with regard to (1) their intrinsically secular nature; (2) the provision of equality of opportunity to compete and the creation of equal conditions of competition (both of which are vital to the establishment of the achievement principle); (3) the specialization of roles in modern sport activities; (4) the rationalization of modern sports through the adoption of standardized rules; (5) the bureaucratic organization of sports to determine rules and manage competitions; (6) the quantification of competition results to establish national and international standards of achievement; and (7) the concept of the record, which was a logical outcome of the quantification of sports. In Guttmann's view, 'primitive' sports were sometimes secular but shared none of the other six characteristics, while Greek, Roman, and Medieval European sports possessed some but not all of these indispensable properties of modern sports.

In contrast, Blanchard, a cultural anthropologist, offered a less historically and culturally fixed interpretation of sport, defining it as "a game-like activity having rules, a competitive element, and requiring some form of physical exertion" (Blanchard, 1995: 9). The broader and narrower uses to which the term sport might be put has been noted by Elias, a sociologist who warned that minimizing the differences and maximizing the similarities between modern sports and the game-contests of antiquity yields a distorted representation of the relationships between them (Elias, 1986: 129–132). Nevertheless, what is included or excluded from definitions of sport may, as Sutton-Smith suggests, tell us more about the purposes of those locked into such definitional exercises than the phenomena they purport to explain (Sutton-Smith, 1995: xii; 1997). Similarly, MacAloon (1987) has observed that the category of sport emerged historically and has varied over time. To insist upon reducing all of the variation this entails in order to shore up a general analytical definition of sport would, in his words, be to risk losing the object "in the act of trying to be sociological about it" (MacAloon, 1987: 106). Paraphrasing Levi-Strauss, he counsels that, in the study of sport, as in the study of anthropology, "the general patterns we seek lie neither in similarities nor differences, but in the *similarities among the differences*" (MacAloon, 1987: 112).

Scholarly writing on sport has, thus, tended to branch in two directions. One is to define the nature of sport and, in particular, 'modern sport' as tightly as possible in order to limit the range of the field and maintain the centrality and significance of certain definitive aspects of these activities. The other is to widen the range of activities to be considered, thereby opening possibilities for identifying previously unrecognized commonalities between different modes of sport and embodied athletic activities. Although some anthropologists work under the aegis of the first approach, which is the preferred one within the field of sport studies, others are drawn to the second. This more inclusive approach affords conceptual space for ethnographic investigation of forms of embodied practice that in some respects resemble and may even reference particular aspects of institutionalized conventional sport activities without needing to be formally labeled as such. Ruling on whether, for instance, practicing a martial art, running in a large-scale civic marathon race, or participating in a figure skating competition meets the threshold for what sport ought to entail is beside the point. When those who engage in a form of embodied practice reckon it to be even somewhat 'like a sport' and themselves to be performing 'like athletes,' it behoves anthropologists to take notice of how these practices, views, and beliefs are enacted and with what effects.

Techniques of the Body

Crucial to the study of sport and related forms of body practice are the ways in which, from one society to another, people not only use their bodies but also acquire embodied techniques that connect the realm of everyday body practices to the public world of shared performances (MacAloon, 1984). Identifying the body as a social as well as psychological and biological phenomenon, Marcel Mauss – a preeminent figure of early twentieth-century anthropology – nominated education (or training) as being dominant among all elements of what he termed the art of using the human body (Mauss, 1973: 73). Proceeding from the concrete to the abstract, Mauss retraced the steps by which he had come to recognize the body as "man's first and most natural instrument. Or more accurately, not to speak of instruments, man's first and most natural technical object, and at the same time technical means, is his body" (1973: 75). Summing up the social dimensions exhibited, for instance, by differing styles of walking, Mauss concluded that there was perhaps no 'natural' way for an adult to walk, but only one or another socially mediated and transmitted form of perambulation.

Mauss's formulation of techniques of the body prefigured foundational aspects of Foucault's (1977, 1978, 1985, 1986) writings on the body as a site of discipline and power as well as Bourdieu's (1984, 1990) commentaries on sport. Mauss selected the Latin word *habitus* as the appropriate one for referencing habits that differ not simply between individuals but especially between societies, educations, class proprieties and fashions: "In them we should see the techniques and work of collective and individual practical reason rather than in the ordinary way, merely the soul and its repetitive faculties" (1973: 73). What Mauss bequeathed to those curious about the social dynamics and meanings of body techniques – including those employed in running, swimming, and dancing – was an analytical framework within which ethnographic observations about the varying ways in which people use their bodies might be linked to larger social processes and purposes.

Augmenting one's capacities to acquire and master specific techniques remains part and parcel of embodied practice within any sport. This may be worked toward by myriad means, ranging from close observation and imitation of the actions of especially respected and accomplished performers to programs of formal instruction directed by coaches, trainers, or masters. Systems of exercise, diet, and rest, not to mention the use of sundry ostensibly performance-enhancing substances, may also be applied to extend the capabilities of athletes and other performers. But it is rarely just bodies that are being targeted for modification.

The regimes of discipline to which athletes explicitly or incidentally commit themselves by opting to play a given sport

or take up a specified form of embodied practice may also be enlisted to sculpt their character and dispositions, first and foremost through the structured training of their bodies. Shaping and preparing an athlete's body may, therefore, be treated as a means for improving not simply embodied performances but also, through these, a person's social behavior and moral worth. This premise underpinned the Victorian doctrine of muscular Christianity, which advocated the melding of Christian evangelism with vigorous and athletic masculinity, diffusing it across the British Empire and beyond (Alter, 2004, 2006; Foster, 2006; MacAloon, 2006). More than a century later, Wacquant (2004) shows how boxers on Chicago's South Side devote themselves to a demanding bodily craft that, nonetheless, distinguishes them locally as persons deserving respect by virtue of their demonstrated self-control. In similar manner, students and practitioners of the Japanese martial art of aikido transfer corporeal lessons and principles imparted during practice sessions to other parts of their lives (Kohn, 2003, 2008). Highly visible body modification projects of the type undertaken by bodybuilders can also contribute to refashioning one's social identity and sense of self (Bolin, 1992, 1997; Klein, 1993; Rapport, 2007).

The social and existential ends to which sport and other forms of embodied practice can be turned by participants and promoters are not readily separable from the techniques of the body through which these are sought. Alongside the possibility that sport might be employed to celebrate cultural ideals or to recast individual lives runs a stream of practical considerations and physical consequences. Activity-induced pain and injuries of various kinds (Howe, 2004) are by no means infrequent experiences for amateur and professional athletes, dancers, and those who 'work out' aerobically or undergo weight training routines. Attentiveness to the workings of one's body is required of those bent on taking part in athletic activities without jeopardizing either their ability to play or their general health. By the same token, addressing and bolstering the performance of bodies shaped by birth defects, serious accidents, or aging become compelling matters for those intent upon participating in sports or other forms of embodied practice in spite of these conditions (Howe and Jones, 2006; Howe, 2011; LeClair, 2009).

Anthropologists have by and large been reluctant to entertain approaches that might prove susceptible to biologically deterministic explanations of human and social development. As mentioned by Besnier and Brownell (2012), one of the challenges initially facing anthropological studies of sport was to unleash these from "essentialized concepts of national character anchored in biological bodies" (Besnier and Brownell, 2012: 444). Recently, however, embodiment has begun to be perceptively interrogated by anthropologists who are charting connections between the sociocultural, biophysical, and neurological facets of sport (e.g., Downey, 2005a,b, 2007, 2010; Sands, 2010). The most striking of these findings are reported in detailed and reflexive ethnographic accounts of what individual researchers have encountered while endeavoring to comprehend and acquire body techniques not previously familiar to them. The difficulties acknowledged by Bourdieu (1990: 166) in articulating "things we understand only with our bodies, outside conscious awareness" are being tackled through what Samudra (2008) has termed as 'thick participation.' Downey's meticulous analyses of the Brazilian martial art of capoeira lead him to conclude that since sensory capacities can in part be cultivated like a skill, practitioners of capoeira are doing more than simply acquiring techniques of the body: they are also tuning their perceptions and actions, thereby creating a culturally and neurologically distinctive way of being (2005a: 98–102, 146, 204–205). The upshot of this for the study of sport is that physical movements and skills are not merely culturally meaningful but also physiologically and neurologically consequential (Downey, 2010). Put another way, biology may be shaped in part by the types of cultural preferences manifested in athletic practices.

Sport as Social Practice

In addition to featuring distinctive techniques of the body, sport produces socially patterned activities engaged in for amusement, recreation, competitive achievement, or, in the case of sport professionals, livelihood. The more-or-less elaborately organized games, competitions, and athletic practices that constitute sport take assorted forms, ranging from individual or team sports, or some combination of the two; competitions staged on playing fields, ice rinks, in swimming pools, and other venues; to games played by recreational, amateur, or professional athletes. When conversing about sport, individuals' affinity for and experience with particular games or forms of athletic practice provide convenient templates. Enthusiasts of, for example, football or ice hockey may not bother to accommodate tennis or taekwondo within their notions of what sport comprises. In contrast, anthropologists, who intentionally expand the domain of games and activities to be considered as forms of athletic practice, introduce a comparative approach into the study of sport activities and relationships. Their inquiries attempt to recognize both the specificity and subtlety of differing types of games and sport forms as well as commonalities and disjunctions encountered across this vast and dispersed field of human endeavor.

An obvious starting point in examining sport as social practice involves disentangling the sets of roles performed in conjunction with athletic events. Along with players, athletes, or competitors, there can also be – depending upon the complexity of a game or sport and the level at which it is being performed – referees, judges, or umpires; coaches, managers, or instructors; club, league, and sport federation representatives, administrators, and event organizers; financial sponsors and sport business personnel; announcers, analysts, and sport media journalists; and, not least, spectators, fans, or viewers of televised sport events. The enactment and coordination of these roles is a central aspect of sport, but how this is accomplished may differ substantially (or not much at all) from one sport or level of competition to another.

The rules of a game or competition are similarly constitutive elements, although these may be stretched or overruled by unwritten conventions invoked by players, officials, or coaches. This happens both in informally organized games and at the highest levels of professional competition. Indeed, as Bourdieu has suggested, a sport, at a given moment,

> …is rather like a musical work: it is both the musical score (the rules of the game, etc.), and also the various competing interpretations (and a whole set of sedimented interpretations from the past); and each new interpreter is confronted by this…when he proposes 'his' interpretation.
> (1990: 163)

Despite differences in how a game or sport may be played by elite, recreational, or child athletes, even glaring disparities can be glossed over if establishing the likeness of these differing forms of a sport takes priority. A rudimentary athletic contest arranged on the spur of the moment can, therefore, be performed as if it was the imagined equivalent of a professional rendering of that sport. Fieldwork-based accounts are most illuminating when these explore the immediate circumstances as well as the broader sporting and social contexts within which particular games and sporting events take place.

Anthropologists have conducted detailed ethnographic studies of sport spectatorship in order to move beyond stereotyped depictions of fans' activities and behaviors. William W. Kelly (2004) reports in Japan not only that baseball fans deport themselves differently than fans of other sports, but also that varying styles of spectatorship can coexist within a single ballpark. In a similar vein, Swyers (2010) explains why merely 'going to a game' is not the same as 'being in the bleachers' at a Chicago Cub's game, where a self-described 'community' of regulars has fashioned perduring relationships and rituals that are demonstrably important to them as individuals. The differing styles and sentiments of self-selecting groups of football fans in England (Armstrong, 1998), Norway (Hognestad, 2003), and Mexico (Magazine, 2007) further establish that being a fan involves exercising choice and creativity in shaping this role to suit distinctive social and sporting tastes.

Sport, Play, and Celebration

No less important than the embodied and social nature of sport is the scope of its celebratory capacities. Because games and athletic competitions constitute forms of play, these stand temporally and experientially apart from mundane aspects of everyday life. Play, as Bateson (1973) argued, is essentially a communicative act. In his well-known example of monkeys engaging in play by pretending to fight, he contends that they share an implicit message: "this is not serious, this is play" (Bateson, 1973: 152ff). What permits such messages, says Csikszentmihayli, "is that play ultimately is a state of subjective experience" that can exist only "where there is an awareness of alternatives" (1981: 19). Distinguishing between playfulness and seriousness depends upon the contexts within which actions occur. The communication of which is which, which is preferred, and by whom, is of primary concern both for participants and analysts. What is marked and celebrated by athletes and spectators are forms of 'play with a purpose' that they choose to celebrate and contrast to the alternatives offered by everyday life.

Meanings generated by or attached to sport are refracted through the playfulness that underpins games and athletic practices. Thus, scoring more goals than one's opponents or defeating competitors in a race or test of physical prowess can be made to stand for larger matters than an ability to kick a ball into a net or to swim faster than others. What can also be brought into play is the celebration of more complicated types of identities and ideals. Sports furnish powerful means for incarnating otherwise abstract and elusive propositions. The stock activities of doing, watching, and debating athletic performances overlap and may be shared between on-field and off-field participants. Athletes are featured performers, but they also observe and discuss the forms of embodied practice within which they participate. Many fans or spectators also possess personal experience of having played the sports they watch as supporters. Among them are those who may have followed their favorite sport for more years than some of the journalists commenting upon a given match or competition. Fans are routinely enjoined to respect the spatial boundaries of events and not interfere with the flow of play, but they are also recognized as key participants in athletic performances. Without them, these would be merely instances of kicking a ball around, running, or skating. There is virtually no sport or form of athletic practice that does not in some manner anticipate its performances being watched and commented upon, whether by fellow athletes, paying fans or conscientious parents and family members. Even a solitary jogger or a group of children playing an impromptu ball game on a street can transfigure what they are experiencing into a performance of sorts by imagining an audience that watches their every move.

This mingling of play and imagination permits athletes, spectators, and event organizers to interweave their respective performances as improvised social drama. Together, they may revel in victories that take the form of prestigious championships, simple wins, or improved performances. But what may also be attended to, beyond the outcome of a given match or performance, is the assertion or transgression of social boundaries. Underlying the staging of any athletic event are potentially divisive questions about the identity and selection of participants: Who will take part? Who will not be allowed to participate? Who might I (or we) refuse to play with or against? Do we regard our opponents as worthy competitors or as persons unlike and beneath us? Matters of race, class, nationality, ethnicity, gender, sexuality, age, or disability can be readily accentuated or ignored within athletic activities, making these matters of intrinsic interest for anthropologists. Tuastad's (1997) essay on the political role of football for Palestinians in Jordan, Klein's (1991) study of the oscillating resistance to American cultural imperialism and dependence upon Major League Baseball (MLB) in the Dominican Republic, Bolin's (1997) account of competitive women bodybuilders' challenges to conventional notions of femininity, as well as Starn's (2011) examination of the golfer Tiger Wood's fall from grace in the world of professional golf and celebrity all show how sporting activities may be tied to extraathletic social distinctions and conflicts.

Ethnographic attention has also been directed to the cultivation and expression of sporting moralities that extend beyond the registering of wins or losses to address matters of aesthetics and cultural integrity. This, in turn, has stimulated analytically innovative conversations between ethnographers

of sport, dance, and other forms of embodied identities (Dyck and Archetti, 2003). For example, Archetti (1999a, 2003) has traced the plurality of male identities and moralities within the popular cultures of football and tango in Argentina, as well as the contrasting standards of heroic masculinity exhibited within cross-country and alpine skiing events in the Olympic Winter Games of Albertville (Archetti, 1999b). Hognestad's (2003) evocation of the endeavors of those Norwegians who opt to support English club teams rather than local football teams reveals this to be a considered stance that distances them symbolically from cloying aspects of Norwegian cultural nationalism. Armstrong's (1998) study of notions of honor and shame among English football supporters, Bromberger's (2007) account of the political restructuring of identities though football in contemporary Europe, and Magazine's (2007) delineation of the anticlientelistic standpoint of fans of the Puma football club in Mexico City illustrates how supporters may prefigure their sporting interests in terms of distinctive schemes of cultural and political preferences. Even within the confines of athletic competitions, elaborate codes and arguments may be applied to reckoning the relative morality of 'fair play,' deception, and breaking the rules, as Mewett (2002) and Nuhrat (2012) have demonstrated.

Sport can also serve as a referent for other social and political considerations. Krauss (2003) recounts how Germany's unexpected championship at the 1954 World Cup competition allowed a defeated people to experience and express pride in the exploits of the men representing them for the first time following the debacle of World War II. In the wake of the Cultural Revolution, it was the Chinese Women's Volleyball team's successive World Championship triumphs that prepared the way for the renewal of sporting and other relations with the world beyond (Brownell, 1995). In Cuba, success in baseball and Olympic sports has become a source of pride for the Cuban people as well as critical matters of state (Carter, 2008). Less exalted modes of participation by former child and youth soldiers in locally organized football leagues in war-torn Sierra Leone have, nonetheless, achieved invaluable social outcomes due to the irresistible attractions of play. The social rehabilitation of those who have been brutalized and who have in turn brutalized others is guided by recognition that the very possibility of games, leagues, and competitions depends upon their individual and collective ability to practice restraint (Richards, 1997).

Sport in Global Perspective

The codification and expansion of organized leisure sports in nineteenth-century Britain, northern Europe, and North America unfolded during a period of rapid industrialization, urbanization, and colonization. The subsequent diffusion of several of these sports to other parts of the world added transnational dimensions to what had initially been local and national forms of athletic practice. For instance, the creation in London in 1863 of the Football Association (FA) gave birth to the world's first national football organization. The launching of the FA Cup competition in 1872 and the Football League in 1888 expanded the structure of the sport in Britain and accommodated its professionalization. The creation of the Fédération Internationale de Football Association (FIFA) in 1904 laid the basis for future international competition, eventually leading to the staging of the first World Cup in 1930. By the late 1930s, more than 50 national football associations belonged to FIFA. Today, FIFA has more member states than the United Nations, making football a thoroughly global sport.

A second sport initiative destined to achieve global reach was inaugurated in 1894 with the creation of the International Olympic Committee (IOC), a nonprofit, nongovernmental organization based in Switzerland. The first Summer Olympics staged by the IOC was held in Athens in 1896, and the first Winter Olympics in Chamonix, France, in 1924. A third major athletic development, the spread of baseball across the United States during and after the Civil War, sparked widespread participation in the game and the founding of professional leagues. Ensuing struggles between team owners to consolidate and control a profitable baseball industry led to the establishing of MLB, a corporate entity that took for itself the power to determine what would be in the 'best interests' of the game. The first MLB championship series officially entitled the 'World Series' was played in 1903 by teams from Boston and Pittsburgh, notwithstanding the fact that baseball had been played in Cuba since 1874 and Japan since the 1880s.

Maneuvering within the specificities of sport histories and practices, anthropologists focus upon the diverse relationships, processes, and meanings that have shaped sport as "a connective tissue of modern life on imperial, international, and global scales" (William W. Kelly, 2007: 79). Bromberger identifies the fascination for football in north-western Mediterranean cities as resting upon its capacity to link the universal and the particular: "On the one hand it symbolizes the prominent values of the modern world: competition, achievement, solidarity, the part played by chance in individual or collective destinies…On the other hand, it offers an opportunity to assert one's collective identity" (Bromberger, 1994: 173). Archetti's (1997a,b, 1998a,b, 1999a) analyses of Argentinian football elucidate its importance in linking a Latin American country to Europe while permitting Argentinians to develop their own preferred style of playing the game. Armstrong and Mitchell's (2008) study of the interpenetration of local and global football in Malta, a small nation on the fringes of the European Union, notes that holding office in a local football club has traditionally served as a springboard into politics. While Malta is hardly a football power, the Maltese Football Association and local teams benefited materially after voting in support of Germany's application to host the 2006 World Cup (Armstrong and Mitchell, 2008: 140).

MacAloon's (1984) appraisal of the Olympics as an institution characterized it in terms of four central performative genres: spectacle, festival, ritual, and games. More recently, MacAloon has deftly dissected the discourse of 'legacy' by examining the ethnography of shifting patterns of Olympic speech among key administrative players in today's 'Olympic Family,' including IOC administrators, candidate city committees, and transnational consultants (MacAloon, 2008). Working outside the corridors of the IOC, a team of Norwegian anthropologists tracked a number of aspects of the planning and staging of the 1994 Winter Games in Lillehammer

(Klausen, 1999a). Pujik's (1999) narrative of the complicated dealings between the local organizing committee and IOC officials in scripting the opening ceremonies for the Lillehammer Games, Berkaak's (1999) description of the erasure of vernacular, local meanings in the completion of key competitive venues for the Games, and Klausen's (1999b) recounting of a fundamental dispute between the hosts and IOC over the organization of the Torch Relay that preceded and opened the Games all serve to illustrate the nature and extent of differences of purpose between these erstwhile partners. Brownell's (2008) study of why hosting the 2008 Games was so significant for China moves beyond prosaic calculations of the costs and benefits of taking on such a responsibility to locate this undertaking within the longer history of colonialism and sport in that country.

Once termed as 'America's Pastime,' baseball has been played intensively for more than a century in several countries and is currently being actively promoted by Major League Baseball International (MLBI) in other national settings for virtually the first time. Anthropological scholarship on transnationalism in baseball has examined the game as it is played in Japan (Kelly, W.W., 2004, 2006, 2009, 2011), Cuba (Carter, 2008; Eastman, 2008b), the Dominican Republic (Klein, 1991), Mexico (Klein, 1997), the United States (Gmelch, 2006), as well as Europe and South Africa (Klein, 2006). Following the IOC's 2005 decision to drop baseball from the Olympics, MLB moved to create its own international competition, the World Baseball Classic (WBC), which is modeled on the FIFA World Cup. The United States has not yet won the WBC on the field, but MLB firmly controls this competition. Klein (2006) and John D. Kelly (2006) have dissected the implications of corporate control through MLBI and the WBC of transnational baseball, linking these to broader patterns of American economic and political hegemony.

In addition to marketing sporting competitions, worldwide media coverage of these, as well as all manner of sport apparel and goods, the globalization of sport entails the migration of athletes – professionals as well as some who are nominally amateurs – across national boundaries. Indeed, 29% of all players listed on the 2005 opening day rosters of MLB teams were born outside the United States (Klein, 2006), while more than 40% of ballplayers with minor league contracts in the United States were foreign-born. An even greater reliance upon foreign-born players exists in the English Premier League, which employs players from across Europe, the United States, Africa, South America, and elsewhere. The transnational movement of athletically talented players to prestigious leagues and wealthy teams in a few focal countries has become a defining feature of a so-called emerging global sporting order. Within this model, embodied talent from more peripheral sporting locales migrates to powerful sporting centers while commoditized sport products and hegemonic sport cultures flow in the opposite direction.

Although attentive to the political economy of sport labor migration, anthropologists have tended to conduct their work in this field ethnographically. Armstrong and Mitchell (2008) show how African footballers may parlay playing for a Maltese team into obtaining Maltese (and, thus, also European) citizenship, thereby facilitating their access to more prestigious leagues in Europe. Besnier (2012) details the arrangements that lead Tongan rugby players and their families to Japan and New Zealand in numbers that may not seem large from the perspective of the receiving teams and nations, but that have deep impacts within Tonga. Dyck (2011) examines the paradoxical pursuit by young athletically talented middle-class men and women – usually with the full support of their parents and coaches – to win athletic scholarships that will take them to American colleges and universities, notwithstanding that most of these families could readily afford to enroll their sons and daughters in Canadian universities. Carter, who has conducted field research both in Cuba and in Northern Ireland, argues that mobility is not so much a personal quality possessed by individual athletes as a highly valued commodity that is produced in the social spaces between where these athletes are initially located and where they intend or wish to arrive (Carter, 2011: 25).

Anthropologists characteristically situate their studies of sport – including those touching on athletic labor migration – in particular settings that they seek to comprehend by taking account of individual and collective aspirations and experiences. By employing this approach, they retain a capacity to notice and look deeply into not only 'big' sports but also an array of decidedly 'nonhegemonic' but, nonetheless, locally preferred sporting practices that other disciplinary approaches are inclined to overlook, if not outright dismiss. Eriksen's (2007) assessment of the factors that recommend certain sports as candidates for 'globalization' also draws our attention to the other end of the spectrum: the considerations that prompt adherents of less recognized or celebrated sporting practices to steadfastly defend the small but viable niches within which these are played and embraced.

The Allure of Sport

The myriad attractions of sports and embodied athletic practices along with the crisscrossing uses to which these can be put make the study of sport a lucrative and intriguing undertaking for anthropologists. The roster of participants who engage with sport in one manner or another is extensive. Governments at all levels recognize the capacities of sport to connect leaders to citizens and, thereby, to promote projects that celebrate the nation (Appadurai, 1995; Brownell 2008), validate the state (Nkwi and Vidacs, 1997; Carter, 2008), or provide readily controllable venues for the expression of civic tensions (De Biasi and Lanfranchi, 1997; Ronsbo, 2003). Sport has also figured in attempts to sponsor the integration of immigrants into their new societies (Dyck, 2007), although it can also be marshaled as a means to marginalize immigrants (Grey, 1992). Sport organizers and institutions, ranging from bodies such as the IOC to MLB to local amateur sport leagues, may harbor wide-ranging if not always fully reconcilable objectives, ranging from public service to earning a livelihood.

Anthropological studies of child and youth sports in Denmark (Anderson, 2008), Canada (Dyck, 2012), Norway (Broch, 2003), and Sweden (Lithman, 2000) speak to the ways in which sport is employed by parents and communities as a means for attending not just to the health and developmental

needs of boys and girls but also to the stated and unstated concerns of the adults and agencies that support these activities. What these studies also reveal are the ways in which child and youth athletes endeavor to work with, against, or around initiatives that others have put into place to shape and manage their participation in sport.

The ways in which sport and athletic practices may be arranged to address, if not always fully satisfy, the varied desires of participants – whatever their age, gender, or level of physical abilities – are virtually infinite. The reasons that anthropologists might wish to look into this field of inquiry remain equally unbounded.

Abstract

Sport history is the sports memory of a nation, but it is a contested terrain because of conflicts over the nature and validity of evidence and the application of theory. It has developed academic societies that publish journals, but there is also a strong tradition of amateur research. Suggestions are made for a research agenda and the direction in which the subject may progress.

Definition of Sports History

Sport history's major contribution to the study of sport is the time dimension. It can be considered the sport memory of a nation: without sport history, there is sporting amnesia. It can set straight the sporting record, but it can also explain why some things changed and why others continued unamended. History can provide the evidence to set events and incidents in their proper context and aid in explanation by giving an awareness of underlying forces. If we want to know where sport is heading, it is useful to know where it has been. It provides the benchmarks for measuring progress and change (or the lack of it). It can help us appreciate the difference between trend and fluctuation and realize that not everything seen as 'important' in sport need have a permanent influence or that everything in modern sport is new. Indeed, the sporting past has shaped the sporting present as all sports have some inheritance from the past, be it rules, governing bodies, styles of play, competitions, or equipment.

Yet it should be emphasized that historical knowledge is always provisional. Apart from 'sportifacts,' showing who won what, where, and by how many, there is no absolute truth in sport history. The sport historian attempts to make sense of the past by finding evidence, interpreting that evidence, and using it to come to a plausible conclusion. However, it should be recognized that sport history is a contested terrain and can be seen from different perspectives, involving diverse interrogations and interpretations of the source material.

Moreover, as Hill (2011: x) points out, 'history' cannot be separated from 'historians,' who have a personal relationship with the subject that can be influenced by upbringing, education, and political beliefs. In his seminal work, Booth (2005: 211) has called for greater reflexivity within the discipline: "an awareness that historians play creative roles in the production and presentation of history," and argues that historians should be more open with their value judgments and acknowledge how subjectivity affects their approach and narrative.

Development of the Subject

There are instances of early academic sport history pioneers who sought "to situate their work with larger societal dialogs and paradigms" (Pope, 1997: 1). Almost a century ago Paxson wrote on the rise of American sports, and the interwar decades saw German academics documenting sources on historical sporting incidents, persons, institutions, and events. However, it was not until the late 1960s that the subject really took off, in association with a general historical move into 'history from below,' which looked at the everyday lives of ordinary people. Almost everywhere two schools emerged, those trained via physical education and those with a background in history. The former focused more on the development of particular sports, whereas the latter was concerned with how sport fitted into the society in which it existed. It was these practitioners who developed sport history into a specialism to rank alongside other emerging 'new' history subdisciplines such as women's history, labor history, urban history, and black history. If chronology and diffusion were the watchwords of the human movement school, then themes and context were those of the historians; to the latter, sport history looked at more than the ludic and placed sporting issues in a wider social, political, economic, or cultural environment. There has been tension between the two schools of thought but generally they have coexisted, often appearing on the same platforms though professing different ideologies. These tensions are set to rise again as sport history consolidates itself in new geographical areas.

Avenues of Communication

Societies

The first major sport history society was the International Committee for the History of Physical Education and Sport (ICOSH) founded in 1967 under the umbrella of the International Council of Sport Science and Physical Education. This quickly became dominated by scholars from Eastern Europe, and ensuing political differences led to a breakaway second organization, the International Association for the History of Physical Education and Sport (HISPA) founded in 1973. Its aim was to establish links between sport historians and all major institutions in sport science – not, it should be noted, with mainstream history. Meanwhile, across the Atlantic, the North American Society of Sport History (NASSH) was established in 1972. In Britain, the British Society for Sports History (BSSH) emerged in 1981 out of a History of Physical Education Study Group, but at its inaugural conference in 1982 it formally adopted its current title. Down in the Antipodes, the Australian Society for Sports History (ASSH) was founded at the fourth biennial Sporting Traditions conferences. The numerical strength of these new organizations and their reluctance to

involve themselves in HISPA or ICOSH posed a threat to the European organizations, which, in a defensive move assisted by the thaw in the Cold War, merged in 1989 to form the International Society for the History of Physical Education and Sport (ISHPES), with less emphasis on the scientific side of sport. Nevertheless, although this society holds conferences around the globe, it has remained Eurocentric in its administration. Another European society was founded in 1995, emerging out of the European Network of Sport Science Institutes of Higher Education. First known as CESH, it formally became the European Committee for Sports History in 2006. Although open to all sport historians, it focuses its efforts on helping young scholars develop a European dimension in their work.

Journals

The first regularly published academic journal in the field was the *Canadian Journal of History of Sport*, which started in 1972 and became part of the Human Kinetics publishing empire in 1995 when it changed its name to *Sport History Review*. It was soon followed by the *Journal of Sport History*, which began as the official organ of NASSH in 1973. In Australia ASSH began to publish *Sporting Traditions* in 1984, which remains the Society's journal. Within Europe, significant sport history journals include *Stadion*, *Internationale Zeitschrift des Sports*, *Revue Internationale d'Histoire du Sport*, *Sportzeiten*, and *Ludica*, funded by the Benetton Foundation, which specializes in pre-twentieth-century material. More recent additions to the outlets for sport history include the CESH-sponsored *European Studies in Sport History* (2008), the Scandinavian-based *Idrottsforum* (2008), and the Brazilian *Recorde* (2008), the latter two both online journals. Two journals devoted to the Olympics, the *Journal of Olympic History* and *Olympika*, are essentially specialized sport history outlets.

By far the most truly global in its coverage is the *International Journal of the History of Sport*, which began life in 1984 as the commercially produced *British Journal of Sports History* but, due to internal political division and a failure to get the publisher to agree to limit subscriptions to members, was not associated with BSSH. In 1987, still under the foundation editorship of J. A. Mangan, it adopted its new title. It now publishes 18 issues a year, including regional ones for Asia, the Americas, Australasia and the Pacific, the Middle East, Africa, and Europe. It also sponsors workshops that lead to special issues of the journal. Initially published by Frank Cass, it is now under the aegis of Routledge. The BSSH's own journal was the *Sport Historian*, which emerged in 1994 out of a newsletter started in 1982. It was renamed *Sport in History* in 2003, around the time that it too began to be published by Routledge.

There are also several sociology of sport journals that open their pages to sport historians, among them the *Journal of Sport and Social Issues*, the *International Review of Sports Sociology*, the *Sociology of Sport Journal*, and a newcomer, *EAST*, which focuses on Asian sport.

Public History

Sport history does not appear only in academic books and articles. There is also what can be termed public sport history, which is generally popularizing, often propagandized, and sometimes entertaining. For a discussion of the topic by leading sports historians who have been involved in public history, see Booth et al. (2008). It has three major forms. First there is what can be termed populist public history, which uses media outlets, particularly television, film, and the Internet. Films and television programs are often criticized by academic historians as the historian's voice becomes mediated by producers and directors who sacrifice historical accuracy for a story line, but this is what attracts the viewers; and far more people watch sport history films or programs than ever read history books. The Internet is often the resort of amateur historians, amassing facts about their favorite team or player and offering constant corrections to Wikipedia entries. More recently, however, a few academic sport historians have opted to put their work online with open access. Whether it gets read by the public is conjectural. Second, we have sport museums, the public face of sport history. These can be the best places to replicate the performance, drama, romance, passion, and emotion of sport, and they have done much to educate through entertainment. Unfortunately, too often they have catered to the nostalgia market and, in doing so, perpetuated myths; lacked historical objectivity and subtlety of argument; failed to contextualize artifacts; eschewed the controversial; concentrated on sport that was competitive, adult, and a male-dominated activity; and had an obsession with winners and winning. A third form is the 'official' history, authorized or commissioned by a governing body or the like. Here the criticism is of both omission and commission: The funders are told what they want to hear, and a spin is often put on controversial issues.

Evidence and Theory

History is an empirically based, interpretive social science: Unless there is some evidence from the past, there can be no sport history. However, the traditional sources of evidence from archives and newspapers – prior to television perhaps "the great instrument of popular communication" (Hill, 2006: 121) – have been supplemented by new ones. Oral history can provide a personal perception of events and what they meant to particular people, giving life to dry historical evidence. Visual material enables us to appreciate what the past looked like. Both film and photography confirm the very existence of the past, with film having the added dimension of movement, the body in action being a central feature of sport. Fiction could be a valuable source as it is a cultural force that shapes how people understand the world around them, but sports historians have been reluctant to use it, viewing it as unreliable and subjective. Nevertheless, novels, particularly those written within the period being studied, can cast light on the context within which sport took place and give insights into matters on which conventional sources are opaque, in particular the role of sport in everyday life.

History is dependent on evidence, though it is important for sports historians to interrogate their sources so as to assess their authenticity and validity. Hill (2006), for one, has stressed that the press should be seen as a text to be interpreted rather than as a factual source to be accepted. Indeed, some aspects of reportage are on a par with inventing tradition: Adding

anecdotes, selecting facts, and forwarding opinion can help sell newspapers but tarnish them as reliable, straightforward source material. Few sport historians have fully embraced the postmodernist view of history being virtually creative writing, but there is a greater willingness to accept that evidence can be prejudiced and can privilege some information above others. What evidence is collected and what is saved can be functions of power in past and present society. Hence subordinate groups – usually people who do not keep diaries, were not on committees, and were not interviewed by reporters – do not always get their voices 'heard' in historical documents. Moreover, 'evidence' can be falsified or manipulated either deliberately with the doctoring or cropping of photographs or more subconsciously when oral history interviewees confuse memory with hindsight.

Booth (2005) takes sport historians to task for a failure to engage more extensively with theory and criticizes those who simply gather facts to tell a story. Yet more sport historians have used theory and theoretical concepts than he gives the discipline credit for. Some sport historians, particularly those from a social history background, have applied theory explicitly in their work, notably that from the European philosophers Antonio Gramsci, Michel Foucault, and Pierre Bourdieu, joining those who earlier had implicitly used the ideas of Karl Marx. Economic historians of sport had always thought in an economically theoretical framework. Many sport historians have indeed embraced theoretical frameworks such as modernization, materialism, hegemony, structuration, feminism, discourse, and textualism and thus adopted the precept of Howell (2007: 461) that "to write good history … requires us to engage critically with the theoretical discourses that shape our historical understanding and to contemplate intellectual trends that can cross disciplinary boundaries." Nevertheless, it is true that few sports historians explicitly discuss theoretical issues; however, many of them are aware of theoretical concepts and theories, which they use to inform their work and help them make their explanations and arguments. Class, status, and power have featured in sport history for a long time, and as new conceptual issues emerged on the sociopolitical agenda, they have been taken up by sport historians. For example, the linguistic turn has entered sport history and the application of cultural studies theory to historical sources is providing an avenue to explore what sport meant to players, officials, and fans. This has had two important influences on sport history. First, it helps us understand more what people believe happened in their sporting experiences, even if it didn't; and, second, it demonstrates how the historical text can influence what people believe happened in sport.

It ought to be noted that two overarching theories have been developed respectively by Guttmann (1978, 2004) and Szymanski (2008) to explain the development of sport. Guttmann postulated sports history's own version of 'modernisation' in which he argued that modern sport possesses seven structural characteristics. First, it was secular with no religious reasons for participation. Second, it should demonstrate equality: Theoretically, everyone should have an opportunity to compete, and conditions of competition should be the same for all contestants. Third, it introduced the idea of specialization: Everyone who wanted to could join in folk football, a sport in which there were no sharply defined roles, but the emphasis on achievement in modern sport brought in specialization both within a sport and between sports. Fourth came rationalization, in particular the development of rules, which in primitive societies were often considered 'divine instructions' (God-given rituals not to be tampered with by mere humans); in contrast nonsecular modern sports have been invented and have written rules. Even more rationalization came via the development of coaching and sports science. His fifth feature was bureaucratization. Almost every major modern sport has national and international organizations that have developed extensive bureaucracies to establish universal rules for their sport and oversee their implementation. These were not required when there were no written rules. Sixth was quantification by which modern sports transform every athletic feat into statistics. Following on from quantification is his seventh point, the modern emphasis on records. Like many models, Guttmann's was an ideal-type postulation that may never have all its conditions fully satisfied. However, it has stood the test of time, if not in its entirety then as a basis on which others have built. Some critics have suggested that the model requires more input on press publicity, marketing, commercialization, and professionalization. Others believe that Guttmann has stuck too rigidly to his original ideal-type model and has refused to revise it in the light of new research findings, though they do acknowledge he has integrated some of the critical perspectives into his own work.

In the early eighteenth century, a movement began in Britain that involved the formation of clubs for many purposes, not least sports such as cricket, golf, pugilism, and horseracing. They enabled people with a common purpose to come together, provided a basis for agreeing common rules and regulations, created a framework for competitive interaction, and secured a location for participation and sociability. Szymanski has argued that modern British sport emerged from these new forms of associativity, which developed autonomously in Britain following the retreat of the state from the control of associative activities. This was in contrast, he contends, to the situation in countries such as France and Germany, where club formation continued to require the explicit or implicit approval of the state. Here, modern sports developed in ways consistent with, or even in the service of, the objectives of the state, most notably the need to maintain military preparedness. His critics acknowledge the ambition of the analysis but suggest missing elements and alternative causal factors. They argue that more evidence is required to support the hypothesis, that he should have looked further back in time for his European material, that he failed adequately to address the issue of class, and that he understated the role of commercialization. More recently, Vamplew (2012) has argued for a study of sports clubs using theories of social, cultural, physical, human, and financial capital.

Finally, it should be emphasized that, until substantiated by evidence, theories are just competing hypotheses. They might aid our understanding, but they do not explain a situation completely. Empirical support is a necessary concomitant for accepting any hypothesis. Moreover, no theory is immutable. If the facts do not fit the theory, then the historian should check the facts again and, if still convinced that the facts are correct, then the theory should be modified. Historians must be prepared to not only use theory but also adapt it.

Research Agenda

The reader keen to know the state of play in the subject is directed to several recent publications. In a series of 'Presidential Reflections' published in the *Journal of Sport History* between 2007 and 2009, past presidents of ISHPES, BSSH, ASSH, and NASSH presented their views on the achievements (and failures) of researchers in their particular domains. Most of the established sport history journals also have issues or detailed articles dealing with the historiography of particular themes. For summaries of the existing knowledge in a variety of countries, readers should consult Pope and Naurright (2010), who provide a comprehensive guide to the international field of sport history as it has developed as an academic area of study. A later publication by Edelman and Wilson (2013) analyzes the state of current scholarship and summarizes ongoing debates but with a wider thematic approach.

Still, much remains to be discovered. Geographically, we know little about sport in Africa or South America. More work is required on the historical diffusion and cultural transmission of sport between nations. Imperialism has long been a major concern of sport historians, mainly focusing on how Britain exported its sports and games to the colonies and how the recipient countries adopted and adapted them. For those who have the languages, similar knowledge is available on French and German sporting imperialism. Outside formal empire, a project based at the University of Cambridge is examining the spread of sport and sports within Europe, with a focus on the various responses to the appearance of foreign sports, including aversion, resistance, adoption, adaptation, and reinterpretation (Tomlinson and Young, 2011). There is also emerging work on America's sporting empire, not merely the sociological emphasis on globalization. However, we need more intracontinental comparisons. The *Journal of Sport History*, the official outlet for NASSH, has yet to publish an article on Mexico, all comparative work being restricted to the United States and Canada. There is also the problem of sport history tending to be conducted within the parameters of the nation state with a reluctance (or an inability) to cross national boundaries. Language can be a barrier but, collaborative work can circumvent this as in the previously mentioned project trying to develop ways of researching a sport history of Europe. Themes such as associativity, gender relations, children in sport, and racial and ethnic participation could all lend themselves to cross-cultural comparisons.

On the economic side, our knowledge is deficient on the production of, and trade in, sporting goods. We know something about the racehorse, whose genealogy dates back to the 1600s, but where did the early cricket bats come from? The demand for a particular sporting good can be volatile, and there is a role here to look at fads and fashion in sporting equipment and apparel. We also know very little about sport sponsorship and advertising by which business firms tried to make potential customers aware of their products. Historically, it existed with sportsmen endorsing cigarettes and various liniments and in brewers painting their names across grandstand roofs, but there have been no studies on either its extent or effectiveness. There is also a great gap in our historical knowledge of sport promoters and entrepreneurs.

Sport history needs its own version of 'history from below' and should look more at the vast range of informal and unorganized sport practices. Much more is needed on noncompetitive sport and on nonelite sport. However, this involves detailed research work with scant academic reward, at least in the short term. To count the number of tennis clubs, defunct and existent, in Nottinghamshire as one amateur enthusiast is undertaking is a painstaking task and still not that useful without similar work for comparative purposes on another Nottinghamshire sport or another county's tennis courts. Although there is a plethora of individual club histories, the concept of the sports club itself, the voluntary organization within which most sport takes place, is worthy of further exploration. This ubiquitous institution took many forms including private sports clubs; work-based ones; those associated with the alcohol trade, religious faiths, politics, education, and the military; and those stemming from local authority intervention into the recreational sector.

This move away from elite sport could also include children's sport, which is relatively untouched. More needs to be done on the role of the family but even that other major socializing agency, the school, has not been adequately explored. Within Britain, most work has looked at the Victorian public schools, though it is still not clear whether the practice matched the rhetoric and how effective the socialization process was. State schools are practically virgin territory, though it is from the pupils of such educational institutions that most professional sportspersons emerged. Some children, such as the boy jockey and child caddy, were actually employed in professional sport. Here there is an opportunity to explore the concepts of child labor (exploitative) versus child work (positive) and the dichotomy between work activities that are socializing and those that are instrumental.

Two sets of concepts that have been researched extensively but still offer opportunities for further work are race and ethnicity and gender. Race and ethnicity have featured, particularly, in studies of the United States, Australia, and South Africa, which have outlined the historical stages of the recognition in white sporting circles of the black athlete. These have involved novelty value, exclusion, segregation, discrimination, and eventually acceptance, though often still carrying stereotyping based on perceptions of black physical ability. The place of women in sport has been extensively covered. For most of the nineteenth century, and well beyond in many countries, half the population faced restrictions on playing sport simply because they were female. Depending on the sport and the nation involved, the mechanisms used included social disapproval from men and women, expert scientific and medical opinion, and the ancillary and regulatory rules imposed by clubs, organizations, and competitions. However, little work has been done on other factors such as the time demands of employment and child-rearing, and preference for other leisure activities. Nor has much been done on women as spectators despite photographic evidence of their involvement. What is now occurring is a recognition that sport and gender is no longer synonymous with sport and women. Masculinities have been added to the gender agenda. Modern sport was established as a male province from its conception and has done much to construct masculinity in many societies. As a site of much male voluntary activity, sport has been a major method of gender fixing.

One failure by historians of sport is to fully grasp the emotion and physicality of sport. It has not been shown what it

was like to be a passionate football supporter in the 1880s or a 'manly' English batsman facing up to the hostile Australian fast bowling in the early cricket test matches. It would be poor history simply to transpose the modern experience of being a fan or a player into the past. Sport historians must search for new source material in match programs, the local press, diaries, and even novels of the time. Somehow we need to hear the voices of the period.

Another issue that ought to be considered is that, to be really representative of sporting participation, sport history ought to take more cognizance of losers, for losing is the most typical of sporting experiences: There can be only one champion, only one cup winner. There is a place for the history of the also-rans: The marathon runners who hit the wall and the Tour de France cyclists who fail to end a stage. Little, too, has been written about those who disliked sport and the reasons for their aversion.

It should be emphasized that there will never be the final word on any topic researched by sport historians, only the best prevailing opinion at a point in time. As Polley (2007: 4) puts it, the past is continually being rewritten "in the light of … current needs and interests": As the cultural climate changes, new ways of looking at historical issues are formulated. Indeed, Howell (2007: 460) has summarized how sport history has changed during his academic career:

> … the now hackneyed iterations of history from below; the flourishing and withering of social control analysis; the flexible cultural Marxism of the sixties and seventies espoused by Edward Thompson, Raymond Williams, and others; the discipline's fascination with Gramscian notions of hegemony; issues of agency; the emergence of subaltern studies; Foucaultian discourses about social technologies, technique and discipline; the excavation of representations and the imagined worlds of past and present; and the cultural and linguistic turn, … All of these have caused changes in the way in which sports historians have gone about their business.

The Future of Sport History

The sport history world is one of plurality with distinct variations in its origins, development, and current state across the world. This was very clear from the discussion at a forum during the 25th anniversary conference of the British Society of Sports History in 2007, at which the presidents of four major sport history organizations presented their views on the state of the discipline in their own bailiwicks. A paper by Hoffman and Kay at the NASSH Congress of 2011 that analyzed the content of sport history journals and conference programs in Germany, Britain, and the United States demonstrated the diversity of approach currently on display within these nations. They cautioned that as scholarly work and knowledge exchange become increasingly international, and sport historians regularly present their findings beyond their own national societies, we should be aware that we are not all singing the same songs at the same time to the same rhythm.

As Pope and Nauright (2010: 3) stated, "sports history is no longer an academic curiosity, but this does not mean that it has joined the mainstream." A major problem facing sport historians is that, although some mainstream historians might acknowledge that "sport is immensely important to any serious attempt to reconstruct a nation's collective life," few read their work (Johnes, 2008: 70). Whereas sport historians think they have much to offer to debates in globalization, race and ethnicity, and particularly identity since "sport helps shape our sense of who we are" (Hill, 2011: 73), mainstream historians, when they bother at all, see sport history as a source of interesting examples but contributing little to the central issues. One reason that they may be unaware of good work is that, till recently, no sport history journal appeared in the Arts and Humanities or Social Science citation indexes. This is changing. The *International Journal of the History of Sport* has just been accepted by Thomson Reuters, and the *Journal of Sport History* by Scopus. Of course, Google may be the salvation of sport history as more articles are scanned into its system. That said, some mainstream journals have published sport history articles. Among other moves toward closer relations is that, in Australia, ASSH has managed to secure a stream within the Australian Historical Association national conference, and the explicit intention of the forthcoming handbook edited by Edelman and Wilson (2013) is to engage effectively with an audience of mainstream historians to whom the work is primarily directed. Hopefully they can be persuaded that sport history offers a "dynamic accessible window into politics, economics, gender, race, class formation, ideology, religion and virtually any discipline" (Pope, 1997: 3).

Some sport historians believe that the way to be accepted by the mainstream is to move down a strongly theoretical avenue. Certainly, this could help establish a beachhead in progressive mainstream history, especially if theory was modified and developed, not just applied. However, the downside is the possibility that it would drastically curtail nonacademic readership who have no time for the theory of Foucault and Bourdieu or theoretical concepts such as hegemony and discourse. They would not necessarily accept that historical perspective is contested terrain with a plurality of meanings and that there are different versions of events depending from whose perspective the narrative is being constructed. Nor might they appreciate Booth's argument that all "facts are propositional statements about the nature of reality" and that all sources distort or filter the truth and all of them need interpretation (Booth, 2005: 30). Such nonacademic amateur sport historians should not be dismissed or abandoned as mere antiquarians. These fans with keyboards may not contextualize well, but they usually get their 'sportifacts' right and provide solid bricks with which academic historians can build their arguments. An exemplar here is Vamplew's (2012) study of the development of the British golf club using over 300 histories of individual clubs written mainly by amateur enthusiasts.

Another way forward would lead sport historians to encompass the broader field of leisure history, which might be progressed by connecting up with histories of taste, leisure, and consumption. Johnes (2008: 69) argues that sport cannot be regarded as special but is just another form of leisure. Sports are physical, but so too are dancing and gardening; sports could be competitive, but so could be baking and music; sport could be social or solitary just like many leisure activities. He adds that "there is surely no emotion or attraction involved in sport that

could not also be found in other pastimes." Moreover, the organization of leisure and sport were both based on clubs with rules and regulations. Some academics would even suggest that some sports might have more in common with other leisure activities than with other sports. Collins has asked what commonality is there between polo at Hurlingham and wrestling in Hull and suggested that it would "make more sense to study them in their own particular social contexts, as activities and manifestations of meaning for particular social groups, rather than as part of the continuum of sport" (Collins, 2007: 399).

Whatever path is taken, none is likely to dominate the subdiscipline. Currently, there are dichotomies between those who opt for quantification and those who prefer a qualitative approach; between those who seek information at the aggregate level (often the quantifiers) and those who look at the individual (mainly the nonstatistical historians); between those who apply theory and theoretical concepts, and those who are more empirically focused; and between those who pose modern questions in a historical setting and those who try to understand what mattered to those in the past. Different schools of sports history can coexist: They did so in the past, and they do so today, so why not in the future?

Abstract

Since the 1960s sport sociology has been a growing and important subfield within sociology. Sport has a significant presence in the modern world that intersects with political, economic, social, cultural, international, national, and local structures and interests. As this brief overview details through its examination of these dynamic and complex relationships, sport sociologists have not established a dominant theoretical paradigm. Rather, they constructed a critical dialogue that has progressively drawn on a range of theories and concepts including: functionalism; Marxism and neo-Marxism; figurational sociology; cultural studies; feminism; postmodern and poststructural perspectives. The field continues to develop as it seeks to explain sport's connections to contemporary issues such as globalization, technological change especially in regard to media technologies, climate change, and sustainable lifestyles.

Introduction

Though the origins of sociological theories and concepts have a clear trajectory starting in the nineteenth century with the writings of Comte, Marx, Durkheim, and Weber, the intellectual history of sociology's interest in sport has more recent origins. There is some debate as to how these seminal theorists viewed the relevance of sporting practices, however, it is reasonable to contend that sport and leisure practices had, by the late nineteenth century, become arenas of sociological interest in that they were established and significant parts of the private and public life. This awareness did not, however, produce any significant levels of analysis and it was not until the 1960s, that a substantive body of sociological theory and research into sport began to be produced. Today sport sociology is a highly prolific field of research and theory constituting a distinctive subdiscipline within sociology. The field is supported by a number of well-established academic bodies (British Sociology of Sport Association, North American Sociology of Sport Association) and peer-reviewed journals (e.g., *The International Review for the Sociology of Sport; Sport and Social Issues; Sport, Education and Society*; etc.) that are also associated with a wide range of annual and quad annual academic international conferences. Across a global span of universities, sport sociology is an essential component of sport science departments and their delivery of undergraduate and postgraduate degrees in sport.

Since the 1960s (Kenyon and Loy, 1965), sociological interest in sport has become extremely wide-ranging and has been informed by the transformative economic, social, cultural, and technological issues impacting the social world. Some of the most influential of these focus on: the impact of globalization and the cultural pervasiveness of competitive sport within everyday social life; the economic power of a globalized (but mostly North American and European) network of intersecting 'sport industries' and transnational corporations; sport's interconnectedness to a growing consumer culture; the intersections between privatized sporting practices and contested power relations across and within a diversity of social groups (class, gender, sexuality, race/ethnicity, disability, age); sport and national identity.

Given this diversity of interests, it is hardly surprising that the field has sometimes been characterized by antagonistic and sometimes acrimonious exchanges between scholars (Giulianotti, 2004). Putting these 'theory wars' to one side, there are a number of concerns that broadly unite the field. One concern has been to analyze and comprehend the social linkages between sports institutional structures and social practices and modernity's evolving institutional and cultural character. Another has been its interest in agency/power dynamics in that as Sugden and Tomlinson (2002: p. 9) note "power relations are social relations."

Sport and Modernity

Social historians, such as Huizinga (1955), evidence the foundational connection between humanity's universal ludic element and the historical development of human civilizations. For Huizinga (1955), the social and cultural characteristics of modernity progressively challenged the playful character of sport as irrational and unproductive and inserted a new rationalism – the dominance of economic and labor relations over all other forms of life. Modernity's structural and ideological frameworks therefore had a powerful influence on modern sport's codification and governance. In the nineteenth century this was particularly exemplified by Victorian Britain that was becoming ever more industrialized, capitalist, urbanized, bureaucratically organized, and internationally interconnected. The confluence of the global influence of the British Empire and its internal processes of modernization created many of the sports that today have a dominant global presence. These sports include, boxing, varieties of football sports (soccer, codes of rugby-football, American football), bat and ball games (cricket, baseball, and tennis), and a family of athletic activities located under the title of track and field.

Though powerful social stratifications based on class, gender, and race were always evident, the growing cultural

significance of these sporting forms (allied to their use in educational settings) created a largely unquestioned process that established belief in the moral virtues and social benefits attainable from such sports (Craig and Mellor, 2010). Located in this realization, sociologists and historians began to analyze how the rationalized elements of modern sport were/are dialectically connected to modernity and how this distinguished it from manifestations of recreational play and games within previous historical epochs. Illuminated by these analyses, it was realized that sport was a highly significant and complex social and cultural construction existing in spheres of being that can be both: physical and abstract, competitive and playful, institutionalized and autonomous, commodified and part of the human commons. Founded on its codified, rationalized, and institutionalized constructions, modern sport's tangible social reality became ever more open to empirical academic analysis. In locating aspects of these analyses within perspectives drawn from Marx, Weber, and latterly Giddens and Bourdieu, sport sociologists have also determined that these social constructions do not and cannot exist other than through their active and reflexive production and reproduction through people's everyday actions. The powerful social bonds connecting fans, athletes, teams, and sporting localities routinely demonstrate that sport is rooted in the norms and obligations of social reciprocity and citizenship. The significance of sport therefore cannot be apprehended in the absence of a much broader understanding of the structure of the society as a whole (Bourdieu, 1986, 1988).

Sport – A Sociological Perspective

For the first half of the twentieth century, sport's nineteenth century genesis meant that in most Western countries sports were run as independent bureaucratic social organizations that were predominantly viewed as having little or no direct connection to the broader processes of democratic organization, governance, and economic prosperity. Regarded mostly as a matter of personal choice and self-interest, sport received minimal interest within the academic sociology of the time. This changed through the latter part of the twentieth century when social, economic, and political transformations and crises drew sport into a sharper sociological focus. These included the postwar rise of the welfare state, civil rights and feminist movements, postcolonial nationalist movements, East–West Cold War ideological and political confrontations. Given its ubiquity, sport could not remain immune from the social movements of the 1960s and 1970s. In the United States, manifestos such as the *Athletic Revolution* (Scott, 1971) and Edwards (1969), a critique of the racialized reality of many sports started to challenge the established consensus. In Europe and Canada, Jean-Marie Brohm (1978) and Rigauer (1981) lead a strong Marxist critique that identified sport as alienated and a bastion of capitalist class inequalities. In the UK, sport became located into social democratic ideas about the welfare state and was increasingly represented as a social right under the 'Sport for All' banner.

Drawing on these critical analyses the field has continued to produce an extensive and important body of social analysis that has its own distinctive genealogy. This genealogy is informed by a number of distinct approaches that parallel sociology's complex and dynamic body of theoretical perspectives and epistemological approaches. Though the major perspectives which have influenced the field remain open to debate (Giulianotti, 2005; Jarvie, 2006), there is a fairly well-accepted consensus that emphasizes the significance of the following perspectives: functionalism; Marxism and neo-Marxism and cultural studies; interpretative approaches; figurational sociology; feminism, postmodernism, and globalization theories. Though the field is often reduced to these perspectives, it is important to state two caveats. While many of sport's most influential theorists are associated with one perspective more than others, none has attained dominance within the field. This is even more apparent when distinctions are made between the epistemological traditions within different countries. Across university departments and academic journals there are distinct differences between the United States, Canada, the UK, and Europe. Moreover within much of the recent literature covering gender, race, sexuality, and sporting bodies, the boundaries between feminist, cultural studies, postmodern and poststructuralist analyses are often arbitrary and fluid, and many would argue that these separations are mostly habitualized academic conventions rather than an artifact of necessary epistemological or ontological coherence.

Given that numerous texts provide those interested in sport sociology with comprehensive discussions and critiques of these perspectives, it is not the intent of this article to provide yet another contribution to this already well-populated area. Instead, the intention is to highlight some of their most salient points within this work. The discussion is organized in three sections. The first reflects on sport's institutional and functional characteristics. The second examines the impact of the critical cultural turn within sociology and specifically how sociology has regarded sport as a cultural product and a set of social practices reflective of dominant and subordinate power relations. The third briefly details some of the emergent themes that are starting to have a presence within sport sociology.

The Institutional Analysis of Sport: *The Functionalist Turn*

Theorists such as Durkheim, Parsons, and Merton influenced much of the initial sociological analysis of sport. In adopting this structural functionalist perspective, this work broadly accepted the premise that the social world could be understood as a system of integrated and interconnected working parts. This work was primarily empirical and focused on establishing 'social facts' and was primarily adopted by American sociologists (Loy et al., 1978). Their goal was to establish if there was empirical proof for popular assumptions regarding sport's capacity to 'function' positively as a social institution and contribute to the Parsonian mandate to achieve necessary functional prerequisites. More specifically their interest was on how sport could integrate members of the society, provide an arena of positive goal setting and attainment of positive and character-building

attributes, make a contribution to the health and well-being of the nation, create community, and foster national identity.

The results were by and large inconclusive (Fine, 1987). By the late 1970s, concerns regarding processes of socialization started to take a more critical turn as the linkages between participation in sport, class and gender inequality, racism, and other socially problematic behaviors (cheating, violence, sexual abuse, etc.) became matters of concern. Contemporary empirical research continues to provide insights into a number of issues: the changing institutional structure of globalized sport (Maguire, 1999); the increasing rapidity and impact of technological change on the world of elite sport performance; the use and regulation of performance enhancing drug use and nontherapeutic surgical body enhancements; and the contradictory representations of the 'natural embodied athlete' (Cole, 2002). The ongoing penetration of computer-mediated technologies to all aspects of modern (or indeed postmodern) life has created a growing interest in the study of how social media is transforming sport (Wilson, 2007); the impact of new forms of control, surveillance, and conformity; the power of networked sport (Sugden, 2002; Castells, 2009).

The Cultural Analysis of Sport: *The Critical Turn*

From the 1970s, sociological research on sport took a critical and ethnographic turn, documenting structural and cultural inequalities within sport, and challenging many of its popular ideological representations. In the UK, this was led by authors, such as Hargreaves (1986), and allied scholars influenced by the Centre for Contemporary Cultural Studies based in Birmingham and in North America by Gruneau (1988, 1999) and others associated with the Massachusetts School. These approaches collectively attempted to re-center the sociological study of sport within a neo-Marxist perspective that retained an overriding concern with capitalist political economy. The theoretical grounding of much of this and other subsequent work (Sugden and Tomlinson, 2002) drew on the work of Gramsci's notion of hegemony. Analyzed through these more critical conceptual lenses, sports were no longer perceived as immutable and traditional entities but as contested social practices produced by athletes and organizers within the context of historically specific social constraints. Underpinned by the hegemony of bourgeois culture, modern sport became regarded as a powerful ideological tool naturalizing the celebration of competition and winning organized by the principles of capitalism (belief in the free market, commodification, Fordist managerialism, and division of labor). Although often hidden by its own institutionalized rhetoric, sport was recognized as a powerful ideological resource whose control was/is essential to the interests of dominant social groups. Also pivotal to this perspective was the idea of resistance. A counterpoint to sport's relative autonomy was that it could be harnessed by subordinate groups to challenge dominant ideologies and structures. Over three decades of research by a substantive international group of sport sociologists has drawn on these perspectives to explore issues of class, gender, race/ethnicity, sexuality, and disability that detail how hegemony is open to contestation and that sport is a powerful social arena in which meaning is not only constructed, but challenged and reconstructed (Craig and Beedie, 2010).

Paralleling the development of cultural studies, Eric Dunning, a student of Norbert Elias cultivated a somewhat different cultural orientation. Dunning incorporated Elias' grand theory of social development into a figurational approach to sport sociology (Elias and Dunning, 1986; Dunning, 1999). The figurational approach focuses attention on social processes and interdependencies that frame a diversity of issues ranging from hooliganism to athlete migrations and male bonding. The figurational approach distinguishes itself from the neo-Marxist and cultural studies perspectives through its comprehensive focus on social structures while taking into account a group processes such as emotions, class, gender and race distinctions, and communication patterns.

During the 1980s, feminist sport theorists such as Jennifer Hargreaves and Ann Hall incorporated aspects of the figurational approach with cultural studies and its emphasis on hegemony and resistance to move the analysis into the examination of gender relations within sport. The distinctive waves of feminist analysis (Hargreaves, 2004) have established a globally influential sociological field within which sport is theorized as a male preserve contributing to the oppression of women physically and sexually. Though this observation represents a fairly simplified summary, the wide-ranging and disparate analyses representing a feminist stance assert two notable principles: that sport offers women the potential for subverting male dominance by enabling women to experience their bodies as strong and powerful; that the dominant constructions of sport can be contested and restructured to align feminist social agendas.

Emerging from this feminist critique has been the necessity to construct a critical understanding of the physicality of sport. Most classical sociological theory either ignored or diminished the social significance of the body. Yet the empowerment and transformation of the body is at the heart of sport's transformative potential. The synthesis of Foucault and feminist theory has enabled sport scholars to problematize the body and establish it as a site of control and domination through which power is exercised and enjoyed (Giulianotti, 2005). While bodies can be empowered through sport, they are also constrained, shaped, consumed, and act as a powerful ideological resource.

A significant development within cultural studies was the inclusion of a range of cultural factors and artifacts as essential to a critical analysis of the social meanings of sporting events. A growing literature offers critical readings of the mediated discourses surrounding sporting events (Whannell,…) and global sports stars such as Michael Jordan and David Beckham within an ever-present celebrity culture (Kellner, 1996; Cashmore, 2014; Smart, 2005). In its expose of the discursive meanings of sport and its analysis of how these narratives do ideological work reproducing and justifying depictions of meaning and presence (plus absence), this still-growing body of literature represents some of the most influential work within the general field. As Cashmore (2013) details, images of black athletes, even those purporting to offer positive images that are intended to subvert racist

attitudes, still retain the potential to reinforce racial stereotypes associating black athletes with crime, drugs, and poverty. The same is also true for many of the normative images of women in sport, which consistently emphasize those athletes who are deemed to be marketable through their sexualized attractiveness and adherence to the norms of heterosexualized femininity while making invisible those who fail to fit this profile.

Partly informed by the feminist critique of sport, postmodern and poststructuralist perspectives started to have a significant influence on the study of sport from the late 1980s and 1990s. Some of the distinguishing features of these perspectives are their rejection of metatheoretical analyses and their 'grand narratives' (Lyotard, 1984) and their replacement by an emphasis on diversity and contingency. In relation to sport, it's proponents (Rail, 1998) recognized the dominance of transient consumer culture and its use of images and spectacles to enculturate individuals and their search for identity into an endless cycle of (meaningless) consumption and illusion (Baudrillard, 1995). Through their use of yearly cycles of professionalized sport and quad annual sporting mega events such as the Olympics and World Cup (Roche, 2000), a dominant and pervasive media culture implodes sport into realms of hyperreality, mass entertainment, commodification, and passive consumption (rather than active participation). At the pinnacle of these processes are the lifestyles and images of celebrity athletes albeit that these lives are often illusionary and fundamentally disconnected from the lives and everyday reality of their adoring fans. Although its analytic presence has now diminished, the principal value of the postmodern and poststructuralist stances was their questioning of the authority of sport sociology's more structuralist and realist approaches.

Although it has retained an interest in sport's location within popular culture one of the responses to the postmodern turn has seen a significant reexamination of the institutions of sport and their structural intersections with political and cultural power structures (Sugden and Tomlinson, 2002). These examinations often focused on the globalized sport industry and its associated global flows of people, ideas, culture, capital, commodities, and technology. Some of the concerns evident in this work have been the impacts on national identity and its coherence within a multicultural world; growing levels of inequality and social instability; the maintenance of sporting traditions and community; equitable sport development.

Sport in the Twenty-First Century: Emergent Sociological Perspectives

As we progress ever deeper into the twenty-first century, sport sociology has a number of emergent challenges that will become more persistent as time passes. The economic crisis of 2008 has created a number of challenges and contradictions facing the global capitalist system (Harvey, 2014; Stiglitz, 2013; Krugman, 2013). In respect to sport these concerns are (re) directing many sport sociologists to return to the issues of inequality and social and economic development. Though concerns about equity, especially in relations to gender and race, will remain highly significant within the field, there is a diversity of emergent transformative processes attracting attention within sport sociology. Some of the most prominent concerns that will frame significant research and analysis over the coming years are the links between the growth of interactive online gaming, social networking sites, and their relationship to the formation and reproduction of sedentary lifestyles; concerns regarding health and well-being especially in respect to the global explosion in levels of obesity; the impact of technological innovations that range across diverse areas of inquiry such as the media and the body – this latter issue is particularly evident through the growing presence of disability sport; public disquiet about sport governance in some of its undemocratic and unregulated power structures within globally important sport bodies such as FIFA and the IOC; finally, sports intersections between its often-abstract globalized structures and the lived realities of its performance within local everyday contexts of life will continue to provide insights into the production of social life in the twenty-first century.

Abstract

Professional team sports have a peculiar economic dimension. One of the main differences between the organization of professional team sport and the market is that in a competitive market firm chooses its level of output to maximize profit. In contrast, sport clubs are limited in their output by the league, which determines the membership and number of clubs and the number of games played in a season. Another peculiar fact is that team owners in US professional team sports have a more profit-maximization goal and European club owners are more interested in win maximization, which results in big financial losses. This results in a different approach and use of measurements. In the closed leagues of the US is uncertainty of outcome (UOO) and competitive balance, the solid fundament of sport economic analyses, which resulted in the introduction of cross-subsidizations such as revenue sharing, salary caps, and drafting systems. In historical times was there also a reserve clause for transferring players between clubs, but this was forbidden by law in both continents and free agency was introduced. In the open leagues of Europe is UOO less important and are most of the fans focused on some major teams who have to compete for the championship. Cross-subsidization is not a main issue and in most countries is their only a collective sale of broadcasting rights.

Introduction

Sport economics is an exponential growing study topic in the academic world. It started in North America with a central and neoclassical focus on professional team sports and diffused first to the UK and then to the rest of Europe and finally to the world. The increasing cash flow in the sector combined with leisure time and purchasing power resulted in the emergence of a new economic industry. Sport as a leisure industry became a hot item and besides the organization of professional sport leagues came topics as the economic impact or feasibility of sport events, financing sport infrastructure, measuring return on investment, and more European items namely, innovation in sports industry, public funding of sport, sport participation in relation to health economics, and social impact of sport, a central topic in academic research.

We notice in American handbooks on sport economics such as *Sports Economics* of Fort (third edition in 2011) and in *The Economics of Sport* (fifth edition in 2014) by Leeds and von Allmen a total absence of recreational sport. On the other hand, we have the European-oriented handbook *Sports Economics: Theory, Evidence and Policy* of Downward et al. (2009) and *Sport en economie: samen in de spits* of Dejonghe, T. (2012) that has as much chapters on participation sport than on professional sport leagues and also contributes on the economics of sports events and infrastructure. The book of Downward et al. (2009) was more or less a successor of *The Economics of Professional Team Sports* by Downward and Dawson (2000), a more European approach of professional team sports. A neoclassical theoretical framework of European and American professional league models is Késenne's *The Economic Theory of Professional Team Sports: An Analytical Treatment* (2007).

In this article, we will only discuss the economics of professional team sports. The 'planned' organization of leagues in North America will be compared with the less rigid organization of Europe.

The Peculiar Economics of Professional Team Sports

Professional team sports can be analyzed from an economic perspective in which labor (mainly players), capital, and land (stadiums and other facilities) are combined by clubs that supply teams to produce a saleable product – the game or contest. To obtain revenue to pay for inputs it is necessary to exclude nonpaying spectators, hence the universal use of stadiums and a traditional suspicion of live broadcasting of sports. For teams to cover their costs each must be guaranteed a minimum number of home games for which tickets can be sold, which suggests 'league' or round-robin tournaments rather than knock-out competitions. As an organizational structure leagues comprise sets of individual clubs, which fall within the broader governance structures. Another difference between the organization of professional team sport and the market is that in a competitive market firm chooses its level of output to maximize profit. In contrast, sport clubs are limited in their output by the league, which determines the membership and number of clubs and the number of games played in a season. The league is a cartel with clubs acting as firms and can be seen as a violation of antitrust laws (Sherman Act (1890) and Clayton Act (1914)). Despite these legal frameworks, there has been little government intervention in sport markets.

There is potential division of interests between league and club because of the existence of the externalities in production. The first publication about economics of professional team sport were articles of Rottenberg (1956) and Neale (1964) about the players' labor market in baseball and the peculiar economics of professional sport in the US. In Europe, came a reaction of Sloane (1971) who noticed the existence of a different professional team sport model in Europe. Those articles created a massive spin-off of research and publication to understand and optimize the professional team sports and their leagues. In the US are most of the interesting questions on the economics of sport related to professional team sport. This results in a focus on the industrial organization of sports in the

major leagues (National Football League (NFL), Major League Baseball (MLB), National Basketball Association (NBA), and National Hockey League (NHL)) and government subsidies on professional sport.

US Profit-Maximizing Objectives versus European Win-Maximizing Objectives

Drawing upon the historical development of professional sports in Europe and the US, most US writers assume that profit maximization is the goal of team owners. In contrast, Sloane (1971) argued that European club owners might more accurately be viewed as utility maximizers (later on referred to as win maximization) where a major determinant of utility is playing success (winning), although profit is important for the club's long-run financial stability. Forgoing profits, and even underwriting losses, therefore suggests that club ownership is an act of consumption more than investment. The impetus to this assumption was the relegation and promotion of hierarchical sports systems in Europe, coupled with the historic desire in European football for success in international competition.

Sloane's (1971) proposed team utility function is

$$U = U\left\{P, A, X, \left(\prod - \prod^{\mathrm{MIN}}\right)\right\}$$

where 'U' is the utility level attained, which depends upon performance on the field 'P,' home attendance 'A,' health of the league 'X,' and on the excess of posttax profit 'Π' over a minimum acceptable level of posttax profit 'Π^{MIN}.' The notion of an acceptable minimum profit reflects factors such as the club's need to secure its long-run future. Any club that has outstanding debt has to display the ability to service that debt. Over and above servicing debt, the club may need to generate an acceptable level of profit; if it is a publicly quoted limited liability company, the directors need to produce enough dividends to keep the shareholders happy. If they cannot, the share price will fall and the company may become the subject of a hostile takeover. In contrast, if a club has access to a sympathetic and wealthy owner (Chelsea with Roman Abramovich, Manchester City with Sheikh Mansour, AS Monaco with Dimitry Rybolovlev, Paris Saint Germain with Nasser Al-Khelaifi, Juventus with the Agnelli (FIAT) family, AC Milan with Silvio Berlusconi, Shakthar Donetsk with Rinat Akhmetov, etc.) or to favorable treatment from local or national government (Real Madrid, Barcelona, AS Monaco) the minimum acceptable level could actually be negative.

Theoretically, one can expect that other things equal an increase in any one of the four factors will make the supporters, the owners, and the management happier. As Sloane notes, the more closely the four explanatory variables are correlated with each other the more probable it is that the predictions of the profit-maximizing and utility-maximizing models will resemble one another. Unless the predictions differ in some readily identifiable manner attempts to distinguish the objectives of teams will fail.

Uncertainty of Outcome and Competitive Balance

The first contributions to the economics of professional team sports stressed the importance of a key externality in professional team sport known as the uncertainty of outcome (UOO) hypothesis. This implies a more or less equal distribution of talent if there has to be UOO and that gate receipts and broadcasting rights depend crucially on UOO of the games played in the league and on the competitive balance in the league. The North American profit-maximization approach defines the UOO as the solid fundament of sport economic analyses and makes competitive balance as the most important item of sport leagues. If the top club always beats the next ranked club, and so on, the games would be exhibitions, not contests, and they would have little market value. Some degree of UOO is necessary in sports, and this uncertainty is greater the more equal the playing strengths of the competitors. Greater equality of playing strengths among the clubs is wealth maximizing. Attendance at games and viewership on television is higher the closer the standings of the clubs are over a season. The acceptance of UOO and competitive balance implies that the market of professional team sports differs significantly from most industries. Competitive balance depends mainly on the comparative financial strengths of the clubs. Teams earn revenue primarily from ticket sales and broadcast fees. The main cost is player payroll. Attendance is determined chiefly by market (city) size and the club's historical reputation. Since teams are located in cities of markedly different size, the prospect of fielding a competitive team depends in part on where the club is located, but also on how revenues are divided up among the clubs. This resulted in a system of cross-subsidization between the clubs in American leagues. In the US, leagues have intervened in sporting labor market or regulated the distribution of club revenues from broadcasting and in some cases of gate receipts. The arguments in the US are that with a distribution of clubs in unequal size markets and with a ban on unilateral relocation of clubs to the more lucrative markets, the more unequal the division of revenue among clubs the less will be the competitive balance within a league. The desire to promote long-run UOO or competitive balance is due to the fear that domination by a few teams may result in a loss of consumer interest, revenue, and profit. The problem is that there is no convincing body of evidence that sports leagues do evolve toward perfect balance. Clearly, if the bigger members of an industry systematically grow more rapidly than smaller ones, and if the process continues, the industry will become more concentrated. If the small firms grow faster, and if the process continues, the industry will tend to become less concentrated. Given enough time, the sizes of all firms (as measured by, say, revenue or assets) would converge on an 'equilibrium' value, although whether this occurs also depends on random factors. This means that convergence or divergence in the relative distribution of revenues would have an impact on competitive balance and could be a support for cross-subsidization.

In Europe, noticed Dobson et al. (2001) for the English Premier League that from the 1920s until the late 1950s there was a period of steady adjustment toward equilibrium. From the late 1950s until the late 1970s it is suggested that there was no tendency to revenue convergence but this occurred from the late 1970s until about 1990 and convergence seems also to have broken down in the 1990s. The authors conclude there may have been two periods of relative equilibrium, followed by two of major change. The causes of these major changes

occurred during a period of marked social change. In the period 1950–1970s, population drift toward southern England and also from the inner city, and increased access to private transport may have been important, as well as the media in the creation of national support for some teams. It also starts about the time that the maximum wage was abolished, forcing clubs to increase admission charges that had been virtually unaltered since the 1920s. The 1990s breakdown of convergence took place against the simultaneous effects of the Bosman Ruling (*see* The Sport Labor Market) that enhanced players' bargaining power, the influx of money from broadcasters, and the setting up of the Premier League. Add the transition to all-seat stadiums and the necessary rise in ticket prices and there are plenty of factors that would be expected to shake up the industry structure. However, in summary it seems is that the UOO hypothesis seems to be rather overworked as a phenomenon that affects attendances in as much that it not ubiquitously important despite the ingenuity with which it has been measured.

Methods of Cross-Subsidization

Another remarkable characteristic of American leagues is the limitation of the number of teams and the absence of promotion and relegation from or toward a hierarchal lower league. These closed leagues in US sport create, with exception of some major metropolitans, spatial monopolies and a latent demand for enlargements of number of clubs in the league. An advantage of this scarcity of supply is that it has been used to leverage public investments for sport facilities. The combination of the US acceptance of cartelization of the closed sport leagues and the 'need' for UOO and competitive balance results in the creation of specific peculiar measurements known as cross-subsidization. An economic rationale for cross-subsidization lies in the market structure of sporting leagues that can be viewed as a producer cartel within which clubs need to compete in sporting terms, but also to cooperate to ensure that the sports are managed effectively. To attain these ends, leagues have traditionally set the terms of sporting competition and have directly influenced the economic aspects of competition, influencing admission price structures, negotiating television deals and sponsorship arrangements, and last, but not least, controlling the terms upon which players may move between clubs.

The Sport Labor Market

While different in detail, leagues have intervened in sporting labor market or regulated the distribution of club revenues. Leagues have attempted to influence the distribution of talent by applying three major types of labor market policy instruments: drafting systems, salary caps, and reservation option arrangements.

The best-known example of *a drafting system* is the 'Rookie draft,' where the weakest teams have in some degree the first pick of the new playing talent at a price that is discounted on the player's market value. The intention of this measurement is that talent will be allocated between the clubs to improve competitive balance. For example, the source of recruitment to the NFL is college football, which comprises amateur players. The reverse draft ensures that every year the professional teams obtain bargaining access to the new crop of graduates in reverse order of how they finish in the professional league. The intention is to give last year's least successful outfits the first option to pick new recruits. Consequently, the weaker teams have the opportunity to enhance their stock of playing talent at a price, that is, probably discounted on the player's genuine market value. Over time the intention is that such a system reallocates talent between the teams to promote competitive balance. Of course, in hierarchical leagues, with promotion and relegation, the replacement of weaker teams with stronger teams reallocates talent in a similar way. There is, however, one potentially major flaw in the thinking behind drafts, or for that matter how promotion and relegation affects talent distribution. For example, in the draft system, despite the opportunity for weak teams to initially sign new, higher quality talent, there remains an economic incentive for the stronger teams to buy them from the weak ones and the weak teams to sell them to the stronger teams. Leaving aside the personal ambitions of players to wish to play for stronger teams, the clubs would have incentives to trade because the players will probably be offered a contract with a wage below their market value by the team allocated first pick in the draft. Consequently, the gap between what the player can earn from the weaker team and the true market value of the player becomes an economic rent over which teams can bargain. The stronger team can offer the weaker team more than they have paid for the player, while not paying the player their market value. It follows that both clubs can make a relative financial gain through the trade. The player may or may not receive some of this gain. This depends upon the contract of the player.

Over their histories, in some leagues, players have been restricted from moving between clubs within a league, the so-called *reserve clause*. Club owners have claimed that reservation of players or the imposition of transfer fees was necessary to maintain financial soundness of small clubs and to preserve competitive balance within leagues. Economists, since Rottenberg (1956) have been very skeptical of this claim and there is no empirical evidence to support it. While it is true that there is a tendency for the best players to migrate to the larger-city franchises, freedom of player movement or restrictions on player-initiated movement have no bearing on the distribution of playing talent within a league (El-Hodiri and Quirk, 1971). Under free agency, players will migrate to the best-paying clubs. The franchises that pay the most are those that expect the largest incremental revenue from those players' performances. Since an increment in the win percent raises revenue more in a large city than in a small city, the best players tend to migrate to the big-city franchises. At issue is whether in a market where player-initiated movement is forbidden (player reservation, transfer fees), would a small-city club keep a star player that it had acquired through a draft or an assignment? On the roster of that club, the player is worth, say, $1 million in incremental revenue. On a large-city franchise, that player's performance is worth, say, $3 million. Without a scrupulously enforced league ban on cash sales of player contracts, the franchise in the small city has an incentive to sell the player's contract to the big-city

club and capture some portion of that $2 million difference in incremental value. Therefore, players are allocated across clubs based on their highest incremental revenue. Whether the player or the club owns the contract (property right) is irrelevant to the allocation of playing talent within a league. That the efficient allocation of a resource is independent of who owns the property right is, of course, the famous Coase (1960) invariance theorem, but the essence of that theorem was discovered independently by Rottenberg (1956) in his earlier paper on the baseball players' market. While the distribution of playing talent is independent of the degree of freedom in the market for players, the distribution of the rents between owners and players is not. The players obtain a much higher share of the rents arising from their scarce talent under free agency than would be so under league restrictions on player-initiated transfers. Under player reservation, player pay is less than the players' contribution to club incremental revenue. Under free agency, the players, ultimately, receive all of the incremental revenue. It is shown that the intrateam salary structure, with its wide pay differential between starting and backup players is rational and wealth maximizing. Competitive balance is value maximizing, also in part, the appeal of professional team sport is the extraordinary playing ability of the athletes. This is demonstrated repeatedly on television and commented on widely. Such feats are value maximizing for the leagues, since they promote interest in the sport. Prior to the mid-1970s, baseball and basketball players could not negotiate freely with more than one team, and this restriction applied in football and in hockey, until more recent times. In European football (soccer), until the Bosman Ruling in 1995, player movement was restricted by the substantial transfer fee that had to be paid to the club owning the player's contract. The result of player reservation in professional team sport was that players were exploited economically by the owners, in the sense that they were paid less than the incremental revenue that their performance brought to the club (Scully, 1974). It is not the case that the athletes in professional sports were poor by any means, since they were paid on average several times a working man's wage. But, their pay was not equal to what they could have earned, if they were free to offer their talent to the highest bidding club. Free agency has led to an enormous explosion in player salaries and in the share of club revenue captured by the players. Concern about the heavy spending of a number of professional clubs across Europe resulted in the introduction in 2009 of UEFA Financial Fair Play measurements. It was hoped that the regulation would lead to a more 'level playing field' by preventing clubs with wealthy owners who make substantial cash gifts to their club from gaining an unfair advantage over other clubs that are run on a more substantial business model. The full implementation of Financial Fair Play was delayed until 2015 by the European Club Association, an independent body representing football clubs at European level.

In Europe, a general principle of EU law, better known as the Bosman Ruling, that discrimination on grounds of nationality regarding EU citizens was illegal and that all citizens are allowed to work in other EU countries under the same conditions, was the start of free agency in sport. The consequence of the Bosman Ruling was that all players at the end of their contract became agents who were free to move at an international labor market. This resulted consequently in the fact that clubs lost their monopsony power over players. On the contrary, market power went to those players who could sell their talents to the team that offered the highest wages. In combination with this power shift, European football faced the elimination of the limitation of the number of foreign players, which resulted in a substantial migration of player talent. The Bosman Ruling made factor mobility of labor possible and resulted in a reallocation of player talent. The arguments of the football federations and UEFA to defend the existing transfer system were that transfer fees are a form of revenue sharing and remuneration of assets and that without these financial compensations clubs would eradicate youth development. Parrish and McArdle (2004) notice that the European Court of Justice foresaw in its verdict alternative possibilities such as 'revenue sharing' and 'salary cap' to maintain or even increase competitive balance. The problem was that this kind of cross-subsidization would be difficult to implement in the structures of European football. This is because open league structures are historically embedded in European team sports. Moreover, UEFA and the national federations never took these alternatives into concern. The academic world, however, countered arguments on the probability of concentration of player talent and decreasing competitive balance. Késenne (1998), for example, indicated that North American sports economists, such as Scully (1989) and Quirk and Fort (1992), analyzed the elimination of the 'reserve clause' in the US, a system comparable to the transfer system before Bosman, in the MLB. Their conclusion, based on existing theoretical and empirical studies, was that professional leagues in the US would benefit if limitations on freedom of players movement were eliminated. Their central argument came from Rottenberg's (1956) article that anticipated on the already mentioned Coase theorem. Rottenberg argued that a limitation through a reserve clause would not prevent migration of talent toward major teams. In Coase's terms the distribution of resources, in this case player talent, would not be affected by the distribution of ownership rights. Translation of these theoretical findings to professional sports means that free movement of players will have no effect on their distribution and was defined as 'the invariance principle' (El-Hodiri and Quirk, 1971). This North American approach was used as an argument to demonstrate that the Bosman Ruling would have no impact on the distribution of talent in Europe. The problem was that the European professional team sports environment did not fulfill the main criteria of Rottenberg namely, that all firms had to be nearly equal if each is to prosper. A fundamental fact that the European court did not consider, at least not explicitly, is that football players do not move around in a common market as long as there are independent leagues. This implies that smaller national leagues in particular cannot afford to keep their most talented players in a free-agency market. Consequently, the transfer fee can be motivated as an instrument to stimulate development of talent in small-market teams. Haan et al. (2007) warned that free movement of players could be the death penalty for many European leagues. According to them, international differences will increase and international competition will become less exciting. Changing structures toward an open labor market in separated product markets resulted in a competitive disadvantage for smaller market leagues and their teams. The introduction of an open labor market resulted in a concentration of talent into the Big 5 (England,

Spain, Italy, Germany, and France) as well as more recently in Eastern European leagues with 'new money' (Russia and Ukraine). The main reason for this divergence is the opening of the labor market with migrating players in separated win-maximizing product markets with almost no revenue sharing. Some sports economists see a solution in a further Americanization of European football, resulting in a European Major League Football that resembles an American Major league, with one of more semiclosed divisions and forms of cross-subsidization such as salary cap and revenue sharing. From an economic viewpoint, creating a European Major League Football would be the natural outcome of the transformation of locally embedded football into a more business- and media-oriented entertainment. This idea, however, stands in opposite of European football culture with its strong relations with local communities, called 'topophilia,' and the existence of historical traditions and rivalries in every country. Dobson and Goddard (2011) also notice that those in favor of a total withdrawal of major teams from their domestic league underestimate the importance of domestic history and tradition as typical characteristics of football identity in Europe. Arnaud (2006) refers also to the tradition of the football fan who wants a 'twin-pillar' structure consistent of a national competition and a European competition. In sum, local embedment and identity are defining characteristics of European professional football. The EU recognized the specificity of sport in its 2007 voted White Paper on Sport where it takes account on the specific characteristics of sport. Hereby, they recognize the specificity of sporting activities, sporting rules, and sport structures. One of these specificities is the need to ensure uncertainty concerning outcomes and to preserve a competitive balance between clubs taken part in the same competition.

On the whole, the introduction of free agency has eliminated monopsonistic exploitation of players in professional team sports. Nevertheless, in the US leagues, pockets of exploitation exist, particularly among promising rookies, journeymen players, and first-round draft choices from the amateur ranks. This is so because there is not complete freedom in the players' market, such as would occur with teams competing for all players by offering 1year or multiyear contracts for their services. New entrants into the professional ranks, if they survive the intense competition for their positions, must wait several years before they are free to negotiate with other clubs.

Salary caps unlike drafting systems directly target the financial cost of talent. Salary caps can either involve fixing the cost of individual and thereby aggregate player costs by establishing a maximum wage or represent a maximum absolute amount that clubs can spend on players in total, or expressed as a percentage of team (or league) turnover. In the US, the NBA, hoping to strengthen weaker teams' finances, adopted a salary cap, after the alternative of gate-revenue sharing was blocked by the combined efforts of the strongest drawing teams. The frequently offered justification for the control of wages and/or wage bills is that, in principle, it makes the best talent affordable to all teams and which will help to produce competitive balance. A salary cap can be hard or soft. A hard cap means that the total wages in a team may not exceed a maximum amount. In a soft cap system may a certain maximum be exceeded in some circumstances but a luxury tax must be paid. On the other hand, there exists a salary floor. That is a minimum amount that must be spend by a team on wages. One mechanism, invented by basketball is the team salary cap, a device that in theory imposes a maximum salary as a percent of gross revenue (and, a minimum percentage that applies to small-city clubs). American football has a team salary cap, and baseball wants one, but has been blocked in its ambition by the players' union who only allowed a luxury tax. Can a salary cap equalize playing strengths within a league? Suppose that a binding salary cap is imposed that fixes player salaries at a certain percentage of league revenues. The marginal cost of playing talent falls under the salary cap from its level under free agency. If scrupulously enforced, all clubs have the same team salary costs, and if there are no information asymmetries about expected playing talent and no differences in coaching quality, all clubs will have 0.500 records. Like the solution of player reservation with a ban on cash sales of player contracts, the distribution of win percents brought about by a hard salary cap is stable, but it is not profit maximizing nor does it maximize league revenue. A large-city team can earn more profit by acquiring better playing talent and a small-market club can earn more by lowering, its level of playing talent.

In basketball, the team salary constraint is relaxed significantly by the so-called Larry Bird exemption. Under the exemption, a team may re-sign a veteran free agent at whatever cost, and not have that player's salary count in the salary cap. This has led to most clubs having player payrolls well in excess of the cap, and this transforms the team salary limit concept into a soft or nonbinding constraint. The Larry Bird exemption was the main point of dispute between the basketball players and the owners, prior to the 1998–99 season. Salary caps have led, also, to creative financial arrangements such as large player signing bonuses relative to annual salary, back-end-loaded long-term player salary contracts, deferred player compensation, and the shifting of revenue from team operations to other, nonteam entities. Sufficient erosion in the constraint of the salary cap, as with a player reservation system with player transfers for cash, can lead to the same distribution of playing talent as is attained with unrestricted free agency.

In Europe is a salary cap in soccer absent and occurs only in the more recent formed professional leagues in rugby and hockey.

Revenue Sharing

If the degree of competitiveness in the players' market does not affect competitive balance, will it be affected by the division of revenue among the clubs? Traditionally, of course, this has concerned the gate revenue – monies paid by spectators at the turnstiles. Because imbalance is created by teams with different revenue bases, which are then spent on playing talent, to redistribute some home-team revenue implies that a greater absolute amount of income is transferred from the larger club to the smaller club, than the other way around. This means that the larger club experiences a net reduction in revenue, while the smaller team a net gain in revenue. As in many other team sports, away-team shares of gate revenue have fallen steadily over the years, and, currently, a variety of arrangements exist in the US ensuring that the home team receives the largest share of revenue. The NFL operates an unusually generous 60/40

split in favor of the home club, while the NBA and NHL have no gate sharing. In European soccer exists currently only gate sharing arrangements in cup competitions.

As far as TV revenue is concerned, in the US local TV coverage provided no revenue for visiting teams although national TV revenue was shared. In European football exists in most leagues a collective bargaining of broadcasting rights and a part of the total sum is been distributed equally among teams. The other part is divided according to recent and/or historical performances and in Italy is a part divided according to the number of attendances and the inhabitants of the local market.

Abstract

Standpoint theory is based on the insight that those who are marginalized or oppressed have distinctive epistemic resources with which to understand social structures. Inasmuch as these structures shape our understanding of the natural and life worlds, standpoint theorists extend this principle to a range of biological and physical as well as social sciences. Standpoint theory has been articulated as a social epistemology and as an aligned methodological stance. It provides the rationale for 'starting research from the margins' and for expanding the diversity of backgrounds and experience represented in scientific communities.

Standpoint theory is a social epistemology and aligned methodological stance predicated on the understanding that, as recent work in science and technology studies (STS) has shown, scientific knowledge of all kinds is irreducibly social (*see* Science, Sociology of). It is characterized by a distinctive 'inversion' thesis according to which those who are marginalized or oppressed, and therefore often discounted as knowers, may be better positioned to understand social relations and a range of other phenomena than those who are comparatively privileged. This thesis underpins research programs within the social and behavioral sciences and offers a rationale for participatory action research (PAR) and community-based participatory research (CBPR) captured by critical race theorists, feminists, and others who advocate 'starting research from the margins.' It has also been extended to the biological and physical sciences by practitioners and STS scholars who are intent on understanding how the social relations that structure scientific inquiry shape research agendas and outcomes across the sciences.

Standpoint Theory's Central Argument

The central arguments for the epistemic advantage of those who are oppressed or marginalized stem from Hegel's 'master–slave' dialectic, Marx's discussions of ideology, and particularly from Georg Lukács' discussion of the privileged standpoint of the proletariat. In his 1922 essay 'Reification and the Consciousness of the Proletariat' (in Lukács, 1971), Lukács argues that the proletariat has the potential to develop a privileged standpoint from which to understand the rationalized structure of commodities and capital. Under capitalism, the bourgeois tend to accept their position as natural and just; their class privilege makes it possible to retain a rationalizing illusion of subjectivity with respect to their own agency. By contrast, Lukács argues, members of the proletariat routinely run up against arbitrary structures that oppress them and remove much of their subjectivity. In this they directly confront the constraining nature of the social relations that sustain capitalism, and the disconnect between these conditions of oppression and its rationalization. They thus have the resources to recognize that the system and its rationalization is a historical product, its contingency masked by legitimating ideology. Louis Althusser and Antonio Gramsci also offer key insights for understanding how the lived experience of oppression can give rise to the formation of a critical standpoint on oppressive social arrangements (Hennessy, 1993). In essence, then, these originating forms of standpoint theory offer an account of the blinding power of ideology and of how it can be overcome (*see* Ideology, Sociology of).

Later standpoint theorists make the case that these insights can be extended to a range of intersectionally defined social locations. Social differentiation along lines of gender and race, for example, also has the potential to put those disadvantaged by systemic inequality in a position to understand its mode of operation and effects with particular clarity. As developed by feminist social scientists and theorists through the 1980s – for example, by Nancy Hartsock (1983), Patricia Hill Collins (1986), Dorothy Smith (1987), and Sandra Harding (1991) – the cornerstone of feminist standpoint theory is a recognition that the rationalization of gender norms as natural reifies social relations, and the observation that direct experience of gender discrimination has been the catalyst for articulating a distinctive perspective on gender relations. Crucially, feminist theorists argue that situated knowledge of this kind does not, in itself, constitute a standpoint (Hennessy, 1993). It is through working against discrimination that it becomes possible to understand the contingency and the unfairness of ideologically rationalized conditions of life that go unrecognized or are unproblematic for those in positions of relative privilege. To the extent that these insights generate a critical standpoint on knowledge production – on the ways in which the institutions and products of science are inflected by systemic inequity and the ideologies that rationalize them – the situated knowledge of the dispossessed becomes relevant to doing and to understanding science.

Criticisms and Elaborations

The central and most controversial claim associated with standpoint theory is that particular social positions have the potential to produce privileged perspectives, not merely other perspectives. This has attracted three lines of criticism: that, to

sustain an attribution of epistemic privilege, standpoint theorists must be committed to an essentialist conception of the social locations and identities of oppressed groups; that they embrace an untenably strong formulation of the 'inversion' thesis, on which subordinate social location, in itself, warrants an automatic attribution of superior insight; and that these commitments entail a corrosive, self-undermining relativism. Although the central tenets of standpoint theory have been developed in diverse ways by its advocates (see the Signs symposium on Hekman (1997)), it is difficult to identify anyone who endorses essentialism or automatic privilege, much less the relativism assumed to follow from these theses. These views are more typically attributed to standpoint theorists, often in the context of the science wars and identity politics debates of the 1990s, than embraced or presupposed by them.

Where the charge of essentialism is concerned, standpoint theorists generally take as their point of departure established critiques of naturalizing (e.g., biological determinist) conceptions of gender and race difference, critiques that demonstrate the historical contingency of these social categories and of the systemic inequalities they underpin. Rather than simply inverting the terms of these constructs, standpoint theorists understand them to function as ideological constructs in terms of which normative gender and race relations are reified and rationalized. In this spirit the assumption that women must all have something in common – some distinctive shared attribute, experience, or situation – has been discredited by feminist researchers; intersectional analyses (studies of the intersections among disenfranchised groups) reveal a great deal of diversity among those who are structurally subordinate. By extension, the proliferation of feminist perspectives militates against any assumption that there is one correct feminist vantage point from which the true nature of gender relations will be revealed. The methodological formulations of standpoint theory associated with Smith and developed by Harding – the recommendations to ask how the 'everyday world' looks to those who primarily operate 'off-stage' (Smith, 1974) and to 'think from women's lives' (Harding, 1991) – signals an early commitment to intersectional analysis and suggests how diversity can be built into standpoint theory.

The converse worry is that if there is no gender-specific experience shared by all women, then there is nothing to ground a distinctive women's perspective or feminist standpoint. Similar concerns were raised in the context of the identity politics debates of the 1990s with respect to race and class identity, and a number of other subject positions that anchor standpoint theories. This objection only holds, however, if it can be demonstrated that systematic social differentiation makes no difference to the experience of those so identified. Socialist feminists like Hartsock and Smith, who developed the framework for feminist standpoint theory in the 1970s and early 1980s, made the case for recognizing the ramifying impact of sex/gender norms on the lives of those socialized as women, shaping the material conditions of their lives, their relations of production and reproduction, and thus their epistemic capacities, their access to epistemic resources, and their credibility as knowers. More recently, feminist and critical race theorists (e.g., Alcoff, 2006; Moya and Hames-García, 2000) have argued that collective identities do not have to be 'quasi-universal' to give rise to distinctive bodies of experience and perspective that can mobilize a critical standpoint. This resonates with Rosemary Hennessy's recommendation that a feminist standpoint be understood as a form of "critical practice"; its ground is not identification with an oppressed social group, but a "disidentifying collective subject of critique," a subject position constituted through systemic analysis of the social production of difference (1993: p. 30). The key point that emerges from this literature is that, although they are contingent historical constructs, systems of inequality structure our lives in ways that generate not just individual but systematic differences in what we are positioned to experience and to know, and in what resources we have for developing critical standpoints on systemic inequality and its effects (Wylie, 2012). Formulated in non-essentialist terms, this structural 'situated knowledge' thesis (Haraway, 1991) is the central tenet of contemporary standpoint theory and the basis for its claims about epistemic advantage on the margins.

The second line of criticism – that standpoint theorists accord automatic and comprehensive epistemic privilege to those who are socially marginal or subjugated – targets the 'inversion' thesis. The objection is that, in itself, the experience of oppression or marginality cannot be assumed to guarantee better, more reliable, and probative knowledge. Most obviously, the oppressed are often kept in their place in part by being denied access to key epistemic resources like literacy, education, and the information necessary to understand the systemic conditions responsible for their oppression (Narayan, 1988), while insider-outsiders may be loath to risk their tenuous status by challenging community norms and can be fierce defenders of the status quo. A strong reading of the 'inversion' thesis is, then, clearly untenable given the structural nature of the situated knowledge thesis that standpoint theorists take as their point of departure: comprehensive epistemic 'privilege' cannot be attributed automatically to those who are oppressed, just because they are oppressed, and standpoint theory cannot provide a cut-and-dried formula for identifying particular standpoints that can be counted on to produce more objective knowledge. It is something of an irony that this second criticism is leveled against standpoint theorists; the case standpoint theorists make for recognizing epistemic advantage on the margins presupposes a robust appreciation of all the ways in which systems of oppression impose significant epistemic deficits on those they disadvantage. Not surprisingly, they typically construe the metaphor of privilege in terms of possibilities for understanding; consequently, the social location of those who are systemically disadvantaged can also be a source of contingent and problem-specific epistemic advantage. As Uma Narayan (1988) develops this point, workers on a production line in a free trade zone have the experiential resources to understand much more clearly than plant owners and consumers exactly how profit is extracted from their labor, but they may not have the resources to grasp the structural conditions that determine the international flow of goods and capital, and keep their wages low.

The third objection, that relativism is inescapable, presupposes the first two objections and is presented as a *reductio ad absurdum* of standpoint theory as a whole. The criticism is that, unless standpoint theorists assume that social standing is, in itself, a legitimate basis for adjudicating knowledge claims,

they have no grounds for claiming that the insights of the oppressed should be taken seriously, much less preferred over those of the privileged. And if they do embrace a strong reading of the epistemic privilege thesis, an untenable relativism follows: standpoint theorists substitute an appeal to political values and interests for considerations of evidence and good reasons in the evaluation of knowledge claims, and by so doing they undermine ideals of objectivity. Moreover, as the response to charges of essentialism indicates, there are multiple forms and experiences of oppression, even within categories such as race, class, and gender, and thus multiple-related political values and interests.

This line of argument presupposes a conventional foundationalist epistemology according to which objectivity is equated with value-neutral, interest-free impartiality and it is assumed that if we give up the conviction that there are universal, trans-historical, and context-transcendent norms of justification, we will have no basis for comparative evaluation of divergent knowledge claims and a debilitating epistemic relativism will be inescapable. Standpoint theorists join a broad constituency of STS scholars and social epistemologists who have made a convincing case for various forms of contextualism (Knorr Cetina, 1981), and they share an appreciation that appeals to context-transcendent norms of justification not only are untenable but also obscure the contingency and interest-specificity of the norms we have come to accept as a measure of objectivity. The polarized opposition between an idealized 'view from nowhere' and self-undermining relativism by no means exhausts the possibilities for adjudicating epistemic credibility (Rolin, 2006). As critics and theorists of oppression, standpoint theorists clearly recognize that effective action aimed at changing oppressive social relations requires accurate, probative knowledge of these conditions, and they are acutely aware of the costs of being wrong. They are suspicious of illusions of certainty wherever they arise, but especially when such illusions mask the interests embodied in dominant modes of understanding. Rather than rejecting objectivity as a regulative ideal, standpoint theorists are more typically intent on reformulating it in terms that take into account the situated nature of scientific inquiry and its extant norms of justification. The self-identified radical social constructionist Donna Haraway joins standpoint theorists in emphasizing the need to take up the challenge of developing a "usable doctrine of objectivity," one that integrates both a recognition that all knowledges are situated and a "no-nonsense commitment to faithful accounts of a 'real' world" (1991: pp. 187–188).

In direct contrast to the relativism with which the theory is charged, standpoint theorists are notable for arguing that the resources of situated knowledge have the potential to significantly improve the reliability and integrity of the claims we ratify as knowledge; its partiality is not necessarily an epistemic liability. Harding, for example, advocates norms of 'strong objectivity' (1991, 1993), a requirement that the assessment of knowledge claims should take into account, not only the primary evidence and reasons presented in their support, but also the conditions under which they have been produced and ratified: the social, historical circumstances that have shaped the interests of practitioners, the institutional contexts in which they work, and the evolving norms of justification in terms of which these claims are warranted. The goal here is not wholesale rejection of authoritative sources of knowledge like the sciences but to calibrate our confidence in them and to determine how they might be improved, especially with respect to scope of applicability and broader impacts. In this spirit, standpoint theorists direct attention to the transformative impact that feminist, race- and class-based, and other such critiques have had on a range of sciences. They note that, time and again, it has been outsiders to the research establishment or 'insider-outsiders' (Collins, 1986) – practitioners who bring an underrepresented and sometimes an explicitly political angle of vision to bear – who have identified gaps and errors in research programs that privileged 'insiders' have persistently missed, raising the epistemic bar on a number of dimensions and opening up productive new lines of inquiry (Wylie, 2003). Although she identifies herself as a constructive empiricist, Helen Longino's proceduralist account of objectivity captures a number of the insights that are central to the lessons standpoint theorists draw from consideration of such cases (Intemann, 2010). Longino (2002) argues that the beliefs we should count as knowledge are those that have been subjected to critical scrutiny from 'multiple points of view'; mobilizing the resources of diversely situated knowers can counteract the effects of insularity and contribute to the breadth and robustness of scientific thinking.

As reformulated in response to critiques of essentialism, automatic privilege, and relativism, standpoint theory is best understood as a conceptual framework, an open-ended set of analytic resources, for addressing jointly descriptive and normative questions about the epistemic effects of oppression (Wylie, 2012). Its point of departure is a situated knowledge thesis, one that presumes the epistemic relevance of systemic conditions of inequality without specifying in advance what their relevance will be in a given context. It directs attention to asymmetries in epistemic circumstance that suggest that the oppressed may contingently accrue important epistemic advantages (not comprehensive or automatic epistemic privilege). In this it counters patterns of epistemic injustice that discount the distinctive experience, perspectives, and hermeneutic resources of those who are socially marginal (Fricker, 2007). And it provides a rationale for the thesis that genuinely inclusive scientific communities are more likely to recognize their own limitations and to produce more balanced and better warranted understandings of their subject domains.

The Domains of Standpoint Thinking in and about the Sciences

There are a number of contexts in which standpoint theory, conceived in these terms, is relevant to the practice of science and to understanding the sciences. We identify two broad domains in which feminist and other genres of standpoint theory have been or can be productively applied.

Content Critiques: From Problem Choice to Framework Assumptions

Contextual values and interests – ideology of various kinds – clearly affect the choice of topics given priority in the

sciences. For example, feminist critiques of sexism and androcentrism in the sciences, developed both by practitioners and STS scholars, have been instrumental in bringing gendered interests into sharp focus; interests that are reflected in and served by the research agendas pursued by a predominantly male research establishment in a wide range of social, life, and physical sciences. Standpoint theory figures both as a catalyst for these critiques and as a framework for understanding them.

Critiques of problem choice are best developed, and their standpoint theory implications most explicit, in the social sciences, where social relations are a direct subject of inquiry. In any number of contexts, researchers influenced by feminist, critical race, and postcolonial theory, as well as related perspectives, have drawn attention to ways in which research agendas in their fields take the attributes, activities and interests of privileged men as the norm, focusing inquiry on questions that concern them. In the case of feminist research programs that took shape in the 1960s and 1970s, critiques of androcentrism catalyzed what initially were 'remedial' interventions aimed at adding women and gender to existing research programs. The women entering anthropology in unprecedented numbers in the 1960s were quick to recognize the need for compensatory ethnography; the lack of attention to women as subjects meant that women's roles and relationships, and their distinctive subcultures and activities, were largely absent from ethnographic narratives. Early critics observed that this inattention reproduced 'dominant male systems of perception'; women's spheres and cultural understandings were considered only insofar as they figured in or were valued by the public languages and worlds of men (Ardener, 1975). In a classic example from history, Joan Kelly-Gadol (1977) objected that the fortunes of women had been left out of account in research on the Renaissance. Economists called into question estimates of national productivity that excluded consideration of the contributions made by women in the form of unpaid labor within the home or within family businesses (Waring, 1988). The standpoint theorist Patricia Hill Collins (1986, 2000[[1990]]) drew on her working-class Black experience to throw into relief the race and class, as well as gendered, presuppositions that pervasively structured sociological research on 'the family.' And, famously, the feminist psychologist Carol Gilligan (1982) challenged Lawrence Kohlberg's influential model of moral maturation on the grounds that it had been based entirely on interviews with boys. This commitment to redefine research priorities also was evident in a substantial shift of focus in primatology, where research had been structured by the assumption that "primate society revolves around males" (Strum and Fedigan, 2000: p. 5); here, a quite literal reorientation of field observation practice generated substantial new data on the roles and activities of female primates.

In all these contexts, critiques of problem choice quickly exposed gender bias in framework assumptions and methodological norms that proved to have much wider implications, calling into question not just localized cases of science gone wrong, but pervasive androcentrism in science as usual – indeed, in some of the best science on offer (Harding, 1986). The feminist anthropologists who turned their attention to the unstudied domestic spheres in which women operated soon called into question the underlying distinction between public and private; the problem with androcentric ethnographies was not just the absence of women but the imposition of ethnocentric categories presumed to be universal that did not begin to do justice to the diversity of gendered roles and relations they were encountering. The questions Kelly-Gadol raised about historical accounts of the Renaissance were intended from the start to challenge the periodization schemes in terms of which history had been written. The Renaissance, she argued, was anything but a period of cultural rebirth, viewed from the vantage point of women; moreover, the "pattern of relative loss for women" that she noted for this period was a direct consequence of its accomplishments and typical for periods of "so-called progressive change" (Kelly-Gadol, 1976: p. 810). Reflecting on women's history more generally, Peter Novick observes that "feminist perspectives in history were as relevant to such male activities as war and diplomacy as they were to realms in which women dominated" (Novick, 1988: p. 496). Likewise, historians, sociologists, and economists have all had to reassess the assumption that the 'household' could be taken for granted as a relatively fixed and uncontroversial unit of analysis. When they attended to gender roles and relations they found conflicts, differences in interest, and diverse social configurations that call into question not only what they had assumed about households, but about labor markets, 'human capital,' and the causes and effects of poverty (Collins, 2000[1990]). As controversial as Gilligan's positive account of a 'different voice' has been, her critique of Kohlberg was pivotal in destabilizing the Piagetian assumption that moral development must follow a single, universal trajectory. Finally, the new data from primatology have not only fundamentally changed our understanding of contemporary primates – bringing into focus the central role of females and the importance of social dynamics other than aggression, hierarchy, and competition – it has also reframed theorizing about human evolution.

This roster of examples could be expanded in any number of directions. As Novick argues for history, critical analysis arising from underrepresented, subdominant subject positions – as defined by race, gender, and class, colonial status and indigeneity, by ableist and heterosexist norms, to name a few – have to varying degrees transformed virtually every field of human, behavioral, and social sciences since the 1970s, throwing into sharp relief the interest and context-specificity of entrenched, seemingly neutral field-defining agendas and framework assumptions. In this respect, standpoint theorists join STS scholars in detailing the myriad ways in which the values that set the research agenda also permeate the research process. Given their central interest in conditions of oppression, standpoint theorists are centrally concerned to understand, as well, the role played by authoritative research in the construction and legitimation of the social world from which these values arise. They attend to what Ian Hacking (1999) refers to as 'looping' effects, by which scientists not only reproduce but participate in constituting and amplifying the social relations that they see in society; they ask not only whose interests are reflected in entrenched research programs, but who benefits and who is harmed.

Such critiques are by no means limited to the social sciences. Consider, for example, the objections raised by the

women's health movement of the 1960s and 1970s to the conventional focus of medical research on the ailments of men, and the presumption that male bodies and disease profiles could stand as the norm for the medical diagnosis and treatment of women. As Londa Schiebinger describes it, feminist activism was responsible for "a great awakening … of mainstream medicine to women's health concerns"; it directed attention, not only to neglected conditions that primarily afflict women, like breast cancer, but also put pressure on medical researchers to take account of ways in which women's health and disease profiles diverge from models based on studies of male subjects (Schiebinger, 1999: p. 113). Heart disease is one prominent example of a well-studied condition, the understanding of which was based until the late 1980s almost entirely on samples of men, even though it concerned the effects of hormones like estrogen. More generally, the practice of relying on all-male samples to test drug safety and efficacy has been a highly visible target of critique, resulting in regulations that now explicitly require the inclusion of female subjects. The AIDS/HIV activism that resulted in the redesign of antiretroviral drug trials is another well documented example in which outsiders to the research establishment played an instrumental role in exposing systematic bias in the direction of research effort (Epstein, 1996). In the domain of technology (*see* Gender and Technology: From Exclusion to Inclusion?), both intended and indirect effects have been the focus of critique. In fact, every field of inquiry has at least some instrumental uses, and many forms of applied knowledge have some relevance to the gendered, as well as race and class, structure of society. Topics within so-called 'pure' physics are connected to military uses, and are funded precisely because of those uses. Those who have the least opportunity to participate in benefits of high status of military engagement suffer disproportionately from the consequences of war.

Contemporary standpoint theory was in large part catalyzed by these interventions. Harding is explicit that the motivation for her early exploration of standpoint theory was the question, "why has the sex/gender system become visible only now?" (the title of Harding's, 1983, essay). She found it striking that on this and many other fronts the sciences had not proven to be self-correcting. Ingrained sexist and androcentric biases had persisted for decades, and the impetus to address these problems – in everything from social relations and sex difference to economic systems and biomedical conditions – was due to external stakeholders whose interests were not reflected in or served by conventional research programs, and to the situated, often explicitly political standpoints brought to bear by the growing number of women and other underrepresented groups who entered the academy in the 1960s and 1970s. But rather than compromising the integrity of the research process, the questions generated by their diverse perspectives often significantly raised the epistemic bar; they subjected entrenched assumptions to newly rigorous critical scrutiny and called for consideration of a wider range of interpretive or explanatory possibilities, new lines of evidence, and undervalued methodological strategies, in the process making substantial contributions to their disciplines' understandings of traditional as well as new subject matters.

This proliferation of standpoints poses a challenge to conventional norms of justification and conceptions of objectivity on at least two fronts: it throws into relief the partiality and interest-specificity of bodies of knowledge that had been presumed objective (in the value-neutral, interest-free sense); and it demonstrates the epistemic contributions that can arise from mobilizing explicitly situated perspectives. Standpoint theorists take up this challenge, articulating the conceptual framework for a research program in social epistemology and STS that responds to this crisis of confidence in conventional norms of justification. It is characterized by the articulation of a situated knowledge thesis that highlights the systemic conditions that configure our epistemic capabilities, by an emphasis on recognizing epistemic advantage on the margins, and by the proposal of alternative conceptions of objectivity. This last includes proceduralist accounts that focus attention on the jointly social and cognitive conditions that ensure the possibility of transformative criticism, and norms of strong objectivity that build an ongoing critical appraisal of the conditions of knowledge production into the adjudication of knowledge claims.

Equity Critiques and Collaborative Practice

To varying degrees, diverse forms of discrimination continue to be a normal part of the working environment in all of the sciences, embodied in everything from the allocation of funds and skewed citation patterns to patterns of workplace segregation, the structure of the tenure system, and the myriad effects of insider networks and hierarchical prestige systems. Equity activists, who, as standpoint theory predicts, are disproportionately members of underrepresented groups, vocally challenge these entrenched practices as unjust and unsupportable in an enterprise defined by meritocratic ideals. Increasingly, however, the impetus for documenting and counteracting discrimination within the sciences is not only a commitment to social justice but also, at an institutional and state level, a concern that the sciences cannot afford to squander trained talent by tolerating entrenched prejudice. Standpoint theorists extend this generic argument for equity, arguing that discrimination exacts more specific costs than a diminution of the pool of trained talent; it robs the sciences of key epistemic resources as well. A growing number of cases bring to light the costs of gender-based discrimination: feminist examples include key discoveries by women that were not recognized for decades, and patterns of workplace segregation and citation bias that conspire to marginalize the contributions from subfields or from disciplinary niches dominated by women. More generally, the recent history of content critiques outlined above draws attention to the pervasive risks of groupthink in socially homogenous, insular research communities. Standpoint theorists join equity activists in making the case for recruitment and training practices, and for reconfiguring reward structures that foster diversity, but they add an epistemic justification for these interventions. They make the case that, although the contributions of researchers drawn from diverse backgrounds cannot be specified in advance, they can be counted on to expand the range of experience – to develop novel heuristics and perspectives on which the scientific community can draw when subjecting its norms of justification and institutional practices, as well as its

best theories, to critical scrutiny. There is ample evidence coming from a cross-section of the sciences – especially the social and behavioral sciences – that this kind of diversity is necessary to ensure the integrity and reliability of the knowledge ratified as scientific.

On this account, standpoint theory is not only a critical practice but also a source of normative insight about strategies for improving scientific inquiry, making it more robust, relevant, and accountable. Dorothy Smith has long insisted that standpoint theory is, above all, a methodology predicated on a commitment to level the hierarchical relationship between researchers and subjects, recognizing the wisdom of those of us who are insiders to the contexts studied by social scientists. This is the principle that underpins the recommendation to "start research from the margins" (Smith, 1974; Harding, 1991). A similar case for recognizing relevant expertise held by nonscientists is also made in a range of biological, medical, and physical sciences. Brian Wynne (1996) details what sheep farmers know about the ecological impact of nuclear fallout that scientists miss altogether in the context of an STS analysis of expertise, and any number of citizen science initiatives, DIY-research communities, and the medical research activists discussed earlier bear witness to the expertise that lay practitioners have to offer fields as diverse as astronomy, genomics, infectious disease research, and field biology.

These principles of recognizing and engaging various forms of expertise that lie outside professional science are perhaps best exemplified by the longstanding traditions of CBPR and PAR. The ideal here is that researchers should work in partnership with nonscientific communities, collaboratively defining the problems they will address and drawing on the expertise of community partners at every stage of the research program. The sociologists Elizabeth Petras and Douglas Porpora (1993) make explicit the standpoint theory rationale for such practice, arguing that PAR practice is motivated not only by a political, ethical commitment to be responsive to and to treat local communities respectfully, but by a recognition that the poor and oppressed bring significant epistemic resources to the table. They are 'epistemically privileged' in ways that can be expected to 'generate knowledge and insights' on a number of dimensions – a "spectrum of theory, methods and substance" (Petras and Porpora, 1993: p. 107) – that represent significant contributions to disciplinary social science. The history of such research in its various forms is detailed with particular clarity in the context of recent debate about CBPR practice in development contexts (Hickey and Mohan, 2004).

Conclusions

Research in STS brings into sharp focus the local and contextual origins of scientific knowledge. However universal the decontextualized results of inquiry may seem to be, they carry with them parochial assumptions, distortions and lacunae that arise from a particular social order. Standpoint theorists take up a particular set of questions and challenges posed by these insights. They engage in a practice of science critique aimed at countering the erasure of the situated interests that shape the sciences, and they are particularly attentive to the role played by dominant systems of knowledge in reproducing and amplifying systems of oppression. At the same time, standpoint theorists are intent on improving scientific practice. They draw a number of critical and constructive lessons from critiques that demonstrate that insular scientific communities are not reliably self-correcting; it often takes the input of 'insider-outsiders' who bring to bear dissonant experience and a critical angle of vision to identify persistent errors and missed possibilities in inquiry. Standpoint theorists make the case for a modest 'inversion thesis,' arguing that a range of epistemic advantages may accrue to those who must navigate the constraints of an oppressive social order from a position of systemic disadvantage. And, on the basis of that thesis, they articulate an epistemic rationale for fostering diverse, representative, and democratic scientific communities; communities in which the integrity and applicability of scientific knowledge requires the input of diverse critical perspectives, including those of nonscientists. This framework for critique and constructive intervention is potentially relevant to all branches of science, inasmuch as scientific inquiry is a thoroughly social process and perspectives that bring into view the effects of social structure are thus valuable throughout the sciences.

Startle Reflex and Health

Terry D Blumenthal, Wake Forest University, Winston-Salem, NC, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

The startle reflex is a response to sudden and intense stimulation in auditory, visual, or tactile modalities and is characterized by a variety of muscular contractions and autonomic responses. The response is most often measured in humans with the motor potential (electromyography) of the eyeblink reflex. This startle eyeblink response is preserved across the life span and is analogous to whole-body startle responses in other animals. Startle is very sensitive to small variations in eliciting stimulus parameters; task situations; personality characteristics; clinical conditions; psychopharmacological agents and their history of use; conditioning; and a variety of other stimulus, person, and situational factors. Startle has been used to investigate many research questions dealing with information processing deficits in a range of health-related conditions.

Introduction

The startle response is most often considered to be a defensive reflex, with aspects of protection, escape, and interruption, elicited by sudden intense stimulation in several sensory modalities. Startle reactivity varies as a function of the eliciting stimulus parameters, but it also varies based on personality and clinical characteristics of the person, as well as task and situational demands. This makes the startle response a very sensitive measure of automatic and intentional processes at rest or during task performance in normal control participants or difficult-to-test populations. As such, it is useful in evaluating information processing in a wide range of situations. With regard to health, startle is most often used to investigate clinical or subclinical conditions involving stress, anxiety, or information processing deficits, although the application of startle methodology is advantageous in a wide range of conditions, as will be elaborated below. Since startle is affected by attention, emotion, arousal, pharmacological changes, and a host of other factors, it can be used to assess variations in those factors.

The Startle Response and Its Modification

The Ubiquity of Startle

Startle is a particularly useful research tool, since this response can be measured across species, across ages within species, and across states within individuals. The presentation of a sudden, intense stimulus will generally result in very rapid initiation of motor activity that interrupts ongoing behavior and serves to either facilitate escape or activate defensive responses. In mammals (including humans), the startle response often involves crouching and limb flexion to protect the back of the neck and rapid closure of the eyelids to protect the eye (Fendt et al., 2001). The same responses can be measured in humans and lower animals, allowing for the use of animal models to investigate human conditions and for the investigation of the physiology and biochemistry underlying these conditions (Eaton, 1984; Davis, 2006).

Startle is also found across the life span and can be measured in the same way from the newborn to the elderly. This allows researchers to use the same response measure to investigate developmental changes in those factors that affect startle responding such as emotion and task performance. Startle is also found in both awake and asleep individuals, increasing its usefulness in studying automatic processing in difficult-to-test populations such as some clinical patients, infants, etc. (Blumenthal et al., 1987).

Another advantage of startle is the fact that it is relatively automatic, thereby avoiding the problem of demand characteristics that can contaminate self-report measures. The very fast latency of this response (less than 50 ms for the eyeblink component) means that the response has already occurred by the time the participant is consciously aware that a startle stimulus has been presented.

Elicitation and Measurement of Startle

The most common way to elicit startle is by the presentation of a sudden and intense sound, although reliable startle can also be obtained with flashes of light, sudden vibration, puffs of air to the face, a tap to the forehead, or an electrical stimulation of the trigeminal nerve or peripheral nerves (Blumenthal et al., 2005). Although startle reactivity can be measured from skeletal muscles and muscles in the neck, the most widely used measure of human startle is the eyeblink response, a measure of the electromyographic (EMG) activity in orbicularis oculi, the muscle that causes the eyelids to close. Eyeblink EMG is the preferred response measure because it is most sensitive (available at lower stimulus intensities), it habituates more slowly and less completely than other motor components of startle, and it is one of the earliest components of startle to appear after stimulus onset. Another important consideration is the very high signal-to-noise ratio of this eyeblink EMG response; since orbicularis oculi does not have muscle spindles, it generates very low EMG at rest relative to the very large response elicited by a startle stimulus. This allows for the reliable measurement of startle responses on single trials, repeated many times in a session, with no need for averaging in order to see the response (Blumenthal et al., 2004). This is also an easy response to measure, requiring the placement of just two surface recording electrodes on the face below the eye, with a ground electrode anywhere else on the body. This electrode preparation can be used across the life span, from newborns to the elderly (Blumenthal et al., 2005).

The startle eyeblink response measured from orbicularis oculi is driven by the facial nerve (CN VII), with input to the motor nucleus of CN VII from the startle center in the brain

stem, the nucleus reticularis pontis caudalis (nRPC) (Davis et al., 1999). The nRPC receives input from auditory, visual, and tactile stimulation, as well as from many other areas of the brain. These inputs can modulate the startle response, which means that startle can be used to index activity in those various brain areas.

Prepulse Inhibition of Startle

In addition to startle being a sensitive measure in and of itself, it can also be used to investigate other processes that are ongoing when the startle stimulus is presented. For example, if the startle stimulus is presented within 30–800 ms after a weak stimulus, called a prepulse or lead stimulus, the startle response will often be smaller than that elicited without that weak preceding stimulus (Blumenthal, 1999; Graham, 1975). This reduction in startle is called prepulse inhibition (PPI) of startle and occurs for prepulses that are as weak as the psychophysical detection threshold and for prepulses that are in any sensory modality (Blumenthal and Gescheider, 1987; Hackley, 1999). This PPI is seen on the first trial on which the prepulse precedes the startle stimulus, even if the prepulse has been presented dozens of times alone before that first pairing, illustrating the fact that this is not a function of learning or warning (Blumenthal, 1997). PPI is seen with presentation of discrete prepulses, but also with gaps in an ongoing background sound (Fournier and Hebert, 2013) or with frequency shifts in a background sound. The degree of PPI is sensitive to various properties of the prepulses, such as intensity, duration, rise time, and bandwidth, which means that PPI might be useful in assessing the processing of these various prepulse properties (Blumenthal, 1999). PPI is also sensitive to a wide variety of individual differences, such as gender and menstrual cycle phase (Jovanovic et al., 2004), and a variety of clinical disorders and personality differences (see below).

Attentional Modulation of Startle

Just as PPI can indicate prepulse processing, as described above, startle reactivity can also indicate direction of attentional resources. PPI occurs when prepulses and startle stimuli are in the same or different modalities, within specific time windows (e.g., 30–800 ms). At longer time intervals, as occurs in some target detection tasks, a startle stimulus occurring in the sensory modality that is the current focus of attention, as in the presentation of an acoustic startle stimulus during an auditory vigilance task, will tend to elicit a larger-magnitude startle response relative to that in a no-task condition (Hackley, 1999). If the task stimuli and the startle stimuli are presented in different sensory modalities, the startle response tends to be smaller (Schicatano and Blumenthal, 1998). The fact that startle reactivity is affected by attentional direction has resulted in startle being useful in assessing the deployment of attentional resources (Hackley, 1999).

Modulation of Startle by Affectively Valenced Stimuli

Just as startle has been used to probe background cognitive processing and direction of attention, it has also been applied to the investigation of emotion. This most often involves a procedure that is referred to as affective modulation of startle (Lang and Bradley, 2013). Startle elicited during the processing of highly arousing unpleasant stimuli is often larger than when neutral or pleasant stimuli are being processed, since both the startle stimulus and the background valence 'match' (both are unpleasant). When the background is pleasant (a valence 'mismatch'), startle is often smaller than that in the neutral background condition. This valence match–mismatch hypothesis has led to a great deal of research in which the defensive startle response is used to index the degree of unpleasantness of whatever background stimulus is being processed when the startle stimulus is presented. This has most commonly involved processing of visual background stimuli (pictures, objects), but has also been demonstrated during the processing of unpleasant sounds and odors, as well as during the imagining of pleasant and unpleasant situations (Bradley et al., 1999).

The relationship between startle reactivity and emotion can also be considered in research on fear and anxiety (Davis, 2006). Pairing a neutral stimulus with a painful stimulus (e.g., electric shock) in a classical conditioning paradigm can result in that neutral stimulus becoming a conditional fear-inducing stimulus. Pairing that conditional stimulus with a startle stimulus can result in larger startle during the subsequent presentation of the conditional stimulus, a result referred to as fear-potentiated startle. The context in which the fear conditioning occurred can itself cause an increase in startle, an example of anxiety-potentiated startle (Grillon and Baas, 2003). These fear- and anxiety-potentiated startle techniques will be discussed in more detail below.

Clinical Conditions

There are several conditions in which abnormal startle reactivity may be an indication of some underlying problem. This abnormality may appear as either hyperreactivity or hyporeactivity to startle stimuli. Abnormalities of startle modulation can also be used to investigate a variety of disorders. We must also keep in mind the fact that 'abnormal startle' can be difficult to determine, since 'normal' startle reactivity, that seen in individuals selected for the absence of any neurological or psychiatric condition, can vary by as much as a factor of 40 across individuals within a study (Blumenthal et al., 2005). Therefore, the distributions of level of PPI in patients and controls, for example, often show considerable overlap.

Startle Syndromes

Hyperekplexia

The most extreme example of excessive startle reactivity is hyperekplexia, involving both larger-magnitude responses and shorter latencies of responding (see Bakker et al. (2006) for an excellent review of startle syndromes). This term is often used to refer to exaggerated startle, although it has been used more specifically to refer to exaggerated startle that is based on a hereditary disorder characterized by abnormal genes that code for a particular glycine receptor. Major hyperekplexia involves both excessive startle responding and muscular stiffness in newborns, whereas the minor form involves only

hyperexcitable startle responding, without neonatal stiffness, and appears later than the major form. Major hyperekplexia also often involves rapid retraction of the head when the nose or upper lip is lightly tapped, and this seems coherent with the defensive retraction aspects of the startle response. Less well-defined cases of hyperekplexia often fall into the category of either 'sporadic' or 'symptomatic' hyperekplexia (see Bakker et al., 2006). As with many neurological disorders, hyperekplexia is characterized by a wide range of symptoms that are more or less pronounced across individuals, appearing at various stages of development, all of which makes labeling or categorizing these disorders difficult. The one common symptom of the hyperekplexia-related conditions is exaggerated startle reactivity. The motor aspects of hyperekplexia are most effectively treated with clonazepam, a GABA receptor potentiator that compensates for the deficit caused by mutations in glycine receptors and dampens startle reactivity.

Culture-Specific Startle Disorders

Bakker et al. (2013) describe a number of hyperstartling conditions that appear to be specific to certain cultures or locations, the most well-known of which is found in Indonesia, in a hyperreactive startle condition referred to as Latah. In addition to larger startle responses, these conditions often involve a variety of other behaviors (other motor behaviors, vocalizations, echolalia, forced obedience, etc.), many of which are stereotypical and similar across cultures. Bakker et al. (2013) compared eyeblink EMG measures of startle in Latah patients with those of matched control participants and found that this measure of startle was larger and more probable in the patients, but no differences in onset latency or habituation were found. However, startle components in the neck and body muscles were more probable and faster in patients, and they habituated more slowly. Bakker et al. report that startle reactivity was greater than normal in these Latah patients but not as pronounced as would be seen in hyperekplexia. Part of the increased startle reactivity attributed to Latah may be due to the higher rate of anxiety disorders in the patients (see below).

Startle Stimulus-Induced Disorders

Bakker et al. (2006) summarize work describing several disorders that can be triggered by exposure to a startle-eliciting stimulus such as epileptic seizures, reflex myoclonus, and startle-induced stiffness. Reflex myoclonus is in some ways similar in appearance to hyperekplexia but tends to be localized to specific muscle groups. Contraposed to startle-induced stiffness, patients with cataplexy may lose muscle tone when exposed to startling stimuli. Two points to take away from this discussion are (1) that abnormal startle reactivity can be seen in a wide variety of disorders and (2) that sudden, intense stimuli, such as those used to elicit startle, can also elicit a variety of other changes in ongoing motor activity, some of which constitute the expected startle motor response, but others of which are less coherent with the traditional startle complex.

Schizophrenia

The human disorder to which startle research has been most often applied is schizophrenia. Specifically, there is strong evidence for a deficiency of PPI in schizophrenics, as well as in the first-degree relatives of schizophrenics and in people who are subclinical for schizophrenia-like symptomology (Takahashi et al., 2011). PPI is often considered to be an operational index of sensorimotor gating (Swerdlow et al., 2008). When patients are compared with normal controls, PPI is often, but not always, less pronounced in the patients, which is thought to reflect a failure of sensorimotor gating. This gating failure is believed to be related to, or indicative of, other failures of gating in these patients such as those that result in cognitive fragmentation and flooding (Braff et al., 2001).

Much recent research has shown that PPI deficits are not limited to schizophrenia but are found in a variety of other clinical conditions (e.g., Tourette's disorder, Huntington's disease, obsessive-compulsive disorder) as well as nonclinical individual differences (e.g., as a function of gender, menstrual cycle, personality characteristics, etc.; Swerdlow et al., 2008). This finding of PPI deficits in other disorders is in part based on the fact that similar symptoms (i.e., gating deficits) may appear across a variety of disorders. Orthogonally, not all schizophrenics show PPI deficits, suggesting that this indicator of gating deficiency may be specific to (and therefore informative of) a subset of this spectrum of disorders. Also, successful treatment of the clinical symptoms is not always paired with recovery of PPI. To summarize, abnormal PPI of startle cannot be used to diagnose any disorder in the schizophrenia spectrum, but this measure, both in humans and in animal models, may be useful in characterizing some of the neurological mechanisms underlying a variety of disorders and conditions.

Anxiety Disorders

With regard to anxiety disorders, startle may be useful in distinguishing between the concepts of fear and anxiety, with fear being more stimulus-specific, short-term, and signaling imminent danger, whereas anxiety involves a more tonic, contextually triggered state. Davis et al. (2010) summarize research that suggests that these two conditions may be based on somewhat different underlying neurological mechanisms, dissociable by measuring startle reactivity in specific circumstances (e.g., a light paired with footshock might come to elicit fear-potentiated startle upon subsequent presentations, but simply being placed in the testing chamber can elicit context-potentiated startle in the rat). Findings analogous to those from animal research investigating fear- and context-potentiated startle (Davis, 2006) have also been shown in human research, with increased startle magnitude in the presence of painful stimuli or conditional stimuli that have been paired with painful stimuli (Lang and McTeague, 2009). As an example of the fact that this parallel is functional but not literal, startle reactivity is potentiated when rats are exposed to light (Davis, 2006) and when humans are exposed to darkness (Grillon et al., 1997), situations that are anxiety-provoking in each species.

McTeague and Lang (2012) review literature dealing with startle reactivity in a variety of anxiety disorders. In the case of posttraumatic stress disorder (PTSD), for example, 'exaggerated startle' has been considered one of many potential diagnostic symptoms, although the definition of 'startle' in this context does not generally depend on the detailed measures of EMG activity described here. However, exaggerated startle is more likely to be seen shortly after a traumatic event, and it is more

likely in more severe cases of PTSD. Also, several researchers have shown that even when baseline startle is no greater in PTSD patients than controls, startle elicited in the presence of trauma-related ('trigger') stimuli is often significantly greater in patients (Grillon and Baas, 2003; McTeague and Lang, 2012). Analogous differences in startle in the presence of 'trigger' stimuli can be seen in patients with eating disorders or in abstaining drug addicts (see below). Also, PPI of startle has been found to be impaired in unmedicated panic patients (Ludewig et al., 2005), obsessive-compulsive disorder patients (Hoenig et al., 2005), and individuals with high trait anxiety (Franklin et al., 2009a).

The affective startle modulation paradigm described above has been used to illustrate the power of phobia-related stimuli to potentiate startle in phobic patients (McTeague et al., 2009). Unpleasant pictures tend to cause an elevation of startle in most people, but phobia-related pictures further increase startle only in people reporting the phobia that is depicted in the picture (animals, blood, etc.). This increased startle reactivity is subsequently decreased back to normal levels after behavioral therapy to treat the phobia (Vrana et al., 1992), suggesting that startle and phobic symptoms may be related and that both may be affected by some forms of therapy.

Stress

Acute stress causes an increase in the activity of the hypothalamus–pituitary–adrenal gland (HPA) axis, which results in a release of cortisol into the bloodstream. One action of cortisol is to dampen further HPA activity via a negative feedback loop. However, repeated exposure to cortisol can also damage neurons in the hippocampus, which may be at the base of some forms of anxiety. Roemer et al. (2009) and others have shown that increasing cortisol increases startle reactivity in humans.

Grillon et al. (2006) showed that a high dose of orally administered cortisol was related to larger fear-potentiated startle responding, whereas Grillon et al. (2011) showed that cortisol increased anxiety but not fear. Also, this exaggerated fear response is attenuated by pharmacological suppression of cortisol in PTSD patients (Jovanovic et al., 2011). However, Miller et al. (2011) report decreased, rather than increased, startle after oral administration of hydrocortisone, whereas Richter et al. (2011) reported rapid disruption of PPI, with no effect on control startle reactivity after injection of cortisol. These studies, among others, suggest that the impact of cortisol on startle and PPI is affected by the dose, the method of administration (injection, oral, intranasal), the characteristics of the participant, and the timing of the measurement of startle relative to administration of the cortisol. To the extent that cortisol is used to model stress, these situational and constitutional factors may also moderate the degree to which stress is reflected in variations in startle reactivity.

Huggenberger et al. (2013) showed that the development of PPI in young infants may be related to maternal stress. They found that the development of PPI of acoustic startle in the first 4 months after birth was attenuated in babies whose mothers reported higher levels of social stress. This may be because the chronic stress of the mother affected the development of the infant prenatally, with PPI changes from birth to 4 months of age indexing the early development of information processing systems.

Stress also has effects on cardiovascular functioning, and some of these relationships have been investigated with the startle response. Schulz et al. (2011) found that the arterial baroreflex, a regulatory feedback loop that relates heart rate to blood pressure via the vagus nerve, can attenuate startle reactivity if the timings of baroreflex activation and startle stimulus presentation are optimal. If stress alters peripheral vasoconstriction and shortens the preejection period (Schaechinger et al., 2001), these effects may be seen in the timing at which baroreflex activity modulates startle responding. In fact, exposing participants to cold pressor stress (by immersing the hand in ice water) has exactly this effect, shifting the optimal interval for baroreflex modulation of startle. This suggests that startle might be useful in identifying individuals who will be more strongly affected by particular stressors. Schulz et al. (2011) also suggest that the cardiac modulation of startle and the impact of stress on this system may be useful in the investigation of psychosomatic interoceptive symptoms, such as heartbeat detection, due to the involvement of common neurological mechanisms in both situations.

Depression

Affective blunting is common in unipolar depression, and these patients also show less-pronounced startle modulation by affectively valenced background pictures (Dichter and Tomarken, 2008). More specifically, Dichter and Tomarken found that when the startle stimulus followed picture onset by 3.5–4.5 s (the temporal relationship that has been shown to optimize affective startle modulation), startle potentiation by unpleasant background stimuli was weak in depressed individuals, and startle attenuation by pleasant pictures was absent in these patients. Dichter et al. (2004) found that the blunted affective modulation of startle is still present after successfully treating depressive symptoms with antidepressant medication. Another study found that the extent to which affective startle modulation is seen is inversely related to the severity of the depressive symptoms (Kaviani et al., 2004). The fact that startle modulation is less pronounced in more depressed patients, even after they have been treated with antidepressants, suggests that startle might be a marker for symptom severity that is not affected by successful treatment of those depressive symptoms. Finally, Vaidyanathan et al. (2014) found that affective modulation of startle was only abnormal in participants who had recurrent depression, being normal in those who had experienced only one depressive episode.

Eating Disorders

The affective startle modulation method has been used to evaluate the emotional impact of food-related stimuli in patients with eating disorders, as well as in nonclinical participants with tendencies toward such disorders. One might expect food cues to be perceived as positively valenced, suggesting that startle should be reduced in their presence. However, the impact of food cues on startle is affected by degree of food deprivation, eating disorder symptomology, and whether the food is perceived as being imminently

available or unavailable. Food deprivation has been found to result in increased startle in the presence of food-related pictures, perhaps due to the induction of an unpleasant frustrative nonreward condition (Drobes et al., 2001). When actual food items, rather than pictures of food, are presented, startle can be decreased in their presence (Hawk et al., 2004), unless the participant is told that the food item, though present in the testing room, would not be available for consumption until several hours later (Rejeski et al., 2010). Startle has also been used to investigate emotional reactivity to body image information, both in pictures (Spresser et al., 2012) and in words (Herbert et al., 2013).

Addiction

Many researchers have used the startle response and its modulation as a way to evaluate the impact of drugs of addiction and stimuli related to these substances. Startle and its modulation have been used to investigate the effects of withdrawal following abstinence, the emotional impact of drug-related cues, and the impact of drugs on task performance. These lines of research have utilized startle reactivity, PPI, and affective modulation of startle as tools for the investigation of drug-related effects associated with caffeine (Flaten and Blumenthal, 1999), tobacco (Greenstein and Kassel, 2010), alcohol (Rubio et al., 2013), heroin (Walter et al., 2011), and cannabis (Mathias et al., 2011). Many of these effects are complicated by such factors as previous level of use, duration of withdrawal, task demands, conditioning history, expectancy, and polydrug use.

Sensory Deficits

One of the great advantages of the startle response is the fact that it can be elicited by stimuli in several modalities. Inputs from visual, auditory, and tactile sensory systems all project to the pontine startle center; therefore, startle can be elicited by sudden and intense flashes of light, bursts of sound, puffs of air, electrical shocks to the face or arm, or taps to the face (Blumenthal et al., 2005). These various inputs interact, summing to yield larger startle when they are presented close together in time. The multimodal sensitivity of startle allows for its use even when one sensory system is impaired, for example, visual startle elicitation in hearing-impaired participants. The fact that startle is affected by a variety of stimulus parameters (e.g., intensity, duration, bandwidth) means that variations in startle might be useful as indicators of variations in sensory processing. This suggests that startle might be useful as a tool for identifying sensory deficits in nonverbal or difficult-to-test populations such as infants (Blumenthal et al., 1987). Even in compliant adults, methods more objective than self-report may be useful in diagnosing and delineating sensory processing deficits. For example, Fournier and Hebert (2013) report that tinnitus can be objectively identified by the application of PPI of startle methodology, wherein the 'prepulse' is a gap in a background sound. In control participants, such a gap inhibits the startle response to a subsequent intense stimulus, but this inhibition is weaker in tinnitus patients, presumably because the tinnitus 'fills in' the gap in the background sound.

Brain Damage

Honeycutt and Perreault (2012) found that startle is intact in patients who have had cortical strokes. In fact, startle responses are often slightly larger in stroke patients than in control participants, perhaps due to the removal of descending tonic inhibition of startle from the frontal lobes. Honeycutt and Perreault used startle stimuli to modulate movement in the dominant arm that was paralyzed due to the stroke. The startle response in this limb appeared as a flexion response, and it was suggested that startle-activated flexion might be useful to the patient in situations in which that flexion is the intended or appropriate movement. However, the startle-activated flexion tended to interfere with a planned extension of the limb in the same patients, although this interference decreased across trials as the startle flexion response habituated.

Williams and Wood (2012) report on affective modulation of startle in traumatic brain injury (TBI) patients and matched controls. Both groups showed the expected startle attenuation in the presence of pleasant pictures, but TBI patients failed to demonstrate the expected potentiation of startle when viewing unpleasant pictures. Finally, Ueki et al. (2006) report that patients with amnestic mild cognitive impairment showed more PPI of acoustically elicited eyeblink startle responses, whereas those diagnosed with Alzheimer's disease showed deficient PPI to the same stimuli.

Many studies have measured startle and its modulation by prepulses and affective stimuli in patients with a variety of neurological and cognitive impairments. The findings vary widely, perhaps based on the rostrocaudal level of the damage and the extent of that damage, differentially impacting the more-or-less or preattentive or attentive processing involved in the particular startle application used.

Nonclinical Individual Differences

Startle and its modulation have been used to investigate a wide range of personality characteristics (see Blumenthal and Franklin, 2009), only a few of which will be mentioned here. PPI has been found to be deficient in nonclinical individuals who show antisocial or borderline personality disorder symptomology (Franklin et al., 2009b), nonsuicidal self-injury (Franklin et al., 2010), and autism spectrum symptomology (Perry et al., 2007). Using the affective modulation of startle paradigm, Hazlett et al. (2007) found greater reactivity in the presence of unpleasant pictures in borderline personality disorder patients than controls.

Startle and Well-Being

Most startle research has focused on its ability to illustrate automatic processing in conditions of disorder or ill health. However, the fact that startle is a defensive response suggests that it might also be a useful measure in studies of adaptability and wellness. The general theme would be that a decrease in startle reactivity might indicate lower activation of emergency systems or reduced reaction to stress. This would be dependent on the reliability of startle in a particular context. Startle may also be useful in indexing the impact of various therapeutic

interventions: If startle decreases after intervention, then the intervention may be useful as a means to decrease stress, HPA axis activity, etc., with startle being an index of usefulness that is independent of self-report bias. A pre–post shift in startle reactivity would suggest that the technique has been effective at some level in decreasing defensive reactivity. Of course, not all successful therapeutic interventions will be paired with changes in startle or its modulation, but this is still a topic worthy of further investigation.

Emotion regulation can involve either suppressing or enhancing emotional processing and responding (Gross and Thompson, 2007). Enhancement of negative or unpleasant emotional responding would be expected to increase startle, especially if the emotion is fear or anxiety, as described above. Startle would also be increased following any manipulation that either increases arousal or focuses attention onto the startle stimulus. For example, Kiken and Shook (2011) report that mindfulness training can reduce negativity bias, a tendency to perceive danger in neutral situations. Therefore, we might expect mindfulness training to also reduce the startle response if arousal and attention can be equalized across conditions.

Conclusion

The startle response has proved to be a very sensitive, relatively noninvasive, and reliable way to quantify information processing, attention, arousal, and emotion, both across individuals and groups and within individuals across time. If startle varies as a function of some clinical condition, intervention method, personality factor, or other parameter, then startle might be useful in investigating that condition, method, factor, or parameter. This has been shown with clinical and subclinical conditions of ill health and may, in the future, prove to be just as true in cases of positive growth and well-being.

Abstract

State and local taxation comprises those taxes that are collected at the subfederal government levels in order to finance state and local public services, assigning some discretion in the determination of rates and bases of these taxes to subfederal governments. The existence of state and local taxes is explainable by the geographical incidence of public services within a federation. In order not to provide wrong incentives for free riding, each individual should pay for the public services consumed and decide on the level of provision. Thus, state and local taxes are imposed to finance state and local public services. Because federal, state, and local taxes already exist, guidelines for the assignment of different taxes to different government levels are necessary. These guidelines are derived by considering different forms of interjurisdictional externalities. Actual tax systems in OECD countries do not, however, necessarily follow these guidelines of optimal subfederal taxation. Since these tax systems are not merely the outcome of historical incidents, political and institutional factors add to the positive understanding which kinds of taxes are used by subfederal jurisdictions.

State and local taxation comprises those taxes that are collected at the subfederal government levels in order to finance state and local public services, assigning discretion in the determination of rates and bases of these taxes to subfederal governments. Consider a nation with different layers of government that are only serving administrative purposes. Each government level only distributes the public services to and collects the taxes from that nation's citizens upon which they agreed at the national level. In such a country, no state or local taxation is necessary since the level of public goods and services is decided upon uniformly for the whole country. This leaves citizens in some local jurisdictions, which prefer more public services than the national average, as much dissatisfied as citizens in local jurisdictions, which prefer less. It is possible to provide public services, the benefits of which are limited geographically and which are not national in scope, at different levels in different subfederal jurisdictions. Enabling citizens to consume publicly provided goods and services at different levels according to their preferences makes everyone better off without making someone worse off. In order to let people, who want to consume more, pay a higher tax price for those state and local services, taxes must be differentiated accordingly between states and local jurisdictions. In such a world with a differentiated supply of publicly provided goods, each individual can reside in a jurisdiction where a certain level of public services is provided to adequate tax prices. The art of state and local taxation is the assignment of different kinds of taxes to government levels such that an invisible hand properly guides a nation in an ideal world to an optimal multiunit fiscal system. This is not necessarily the case in the real world and some answers exist why fiscal systems are not optimal.

The Rationale of Tax Assignment to the State and Local Levels

The basic idea of a power to tax for states and local jurisdictions is that their public goods and services should be financed by those citizens benefiting from them and deciding on their quantity and quality. In this case, individuals choose their place of residence according to their preferences and their dislike for congestion. A set of fiscal jurisdictions consisting of equal taste communities then results from a process of 'voting by feet' (Tiebout, 1956). Olson (1969) calls the basic condition for such an outcome the 'principle of fiscal equivalence.' It requires assignment to which public goods and services should be provided at which level of government. The guideline for this decision is the geographical incidence of those benefits and the costs borne by citizens in order to finance them. As some public goods and services reasonably cannot be provided at the local level, some kinds of taxes may not be assigned to the local level for good reasons, too.

There are numerous reasons why the proper assignment of tasks and the power to tax to the subfederal levels are crucial to avoid suboptimal outcomes. For example, take the Scala in Milan, the famous Italian opera house. As it is partly financed by user charges and partly by subsidies paid from general taxes of the city, it will be congested because residents living in the suburban towns are able to visit it paying only the user charges and thus a lower price than the city's citizens. Nonresidents receive some of the benefits from the public service without paying an adequate tax price. This spillover is one of the externalities that Gordon (1983) summarized in his treatment of an optimal tax system for subfederal jurisdictions. Another externality exists if nonresidents pay some of the taxes of state or local jurisdictions. Taxes are exported to nonresidents and state and local governments thus have an incentive to provide public services at a higher level than their residents prefer. An example of tax exporting can be found in the taxation of tourist trade or of natural resources in some US states. For the year 1962, McLure (1967) estimated for the US states that overall tax export rates were between 19 and 28% in the short run. In the long run, only 10 states exported more than 24% of their taxes or less than 16%. The estimates are corroborated in a more recent study by Metcalf (1993). Mieszkowski (1983) estimated the 'total waste' in Alaska in the beginning of the

 http://dx.doi.org/10.1016/B978-0-08-097086-8.71026-9

1980s that accrued from excessive public revenues and expenditures that were possible because of high natural resource taxes to about $500 million or 13% of estimated petroleum revenues. Tax exporting is not limited to commodity taxes or natural resource taxes. It may also occur if individuals, firms, or capital are mobile.

If factor mobility is allowed for, the problems of subfederal taxation are even enhanced. If a state or community levies a higher personal or corporate income tax than its neighboring jurisdictions, its mobile citizens or firms emigrate (or move their capital there) in order to enjoy a lower tax burden. Such a situation is characterized as tax competition. In doing so, mobile factors reduce the tax burden of residents and firms in the state or community they move to and increase the tax burden in those jurisdictions they leave. These changes in tax burdens usually are not considered by public authorities in these jurisdictions when deciding on the level of public goods and services such that these are provided at a lower than 'optimal' level. Since there is a local loss from taxation that does not correspond to a social loss, the cost of public services is overstated and jurisdictions will tend to underspend on state and local public services. Buchanan and Goetz (1972) call this effect a fiscal externality.

The effects of tax competition among states and local jurisdictions are similar to those of international tax competition and they vary according to different degrees of mobility of individuals and firms, to the number of mobile factors, to the number of jurisdictions involved in that competition, on the size of the jurisdictions involved, and to the number of tax instruments available to tax authorities. The assessment of the usefulness of these effects becomes rather complicated if competition using tax instruments is complemented by competition using public expenditures, like subsidies or specific infrastructural services, but also tax expenditures like tax holidays to attract mobile production factors.

The impact of tax competition on the possibilities of state and local governments to redistribute income by tax-transfer schemes is relatively clear-cut. Stigler (1957) already stated that "redistribution is intrinsically a national policy." Suppose that a region adopts a progressive income tax program designed to achieve a significantly more egalitarian distribution of income than exists in neighboring jurisdictions. If rich and poor households are mobile, such a program would create strong incentives for the wealthy to move out to neighboring jurisdictions. In this case, local redistribution induces sorting of the population, with the richest households residing in the communities that redistribute the least by income taxes. A more equal distribution of income would result, but it would be caused largely by an outflow of the rich and a consequent fall in the level of per capita income in the jurisdiction under consideration (Oates, 1972). At the central level, this problem does not occur, because mobility is reduced, the larger a jurisdiction.

There are not many theoretical arguments against this line of reasoning. Most of them rely on imperfect mobility of individuals. But the more mobile people become, the better this mechanism should work, the less possible should state and local redistribution by a progressive income tax be. However, according to Buchanan (1975), all individuals have an incentive at the constitutional stage to agree to income redistribution because they are fundamentally uncertain about their future positions in income, health, and employment. At the post-constitutional level the rich might agree to income redistribution by the government because they, first, are interested in a public insurance scheme against fundamental privately uninsurable risks for themselves and their children, and, second, against exploitation by the majority of the poor residents and increasing crime rates. Particularly the second reason is important for the rich: they pay a premium for obtaining social peace. Janeba and Raff (1997) argue that individuals will agree to decentralized income redistribution because it is a credible commitment of the poor majority to the rich minority that the latter is not exploited at the postconstitutional stage. The rich allow for the agreed extent of redistribution because a constitutional competence for income redistribution at the federal level leads to a larger public sector with more income redistribution. From this perspective, decentralized redistribution might be possible and even more efficient since redistribution is closer to citizens' preferences.

Guidelines for a Reasonable Tax Assignment

This reasoning leads to some guidelines for tax assignment of different taxes to the state and local levels. The bottom line is that state and local jurisdictions should finance the services they provide by charges or quasicharges to the beneficiaries (Musgrave, 1983) or they should use those tax bases which have low interregional mobility (Wildasin, 1980). Land and natural resource taxes and to a lesser degree also real estate taxes are thus especially suited for purpose of state or local taxation. A property tax, for example, is a good candidate for being assigned to the local level at least as far as residential property instead of business property is taxed. A property tax is basically a tax on land and construction built on it and it can thus be considered to be a tax on a relatively immobile tax base.

Consumption taxes are inappropriate at the local level because the interjurisdictional mobility leads to cross-border shopping or tax exporting, but they become suitable for the state level if the region is large enough. However, the technological development, in particular Internet shopping, reduces the possibility for state governments to levy a tax upon consumption. If individuals, firms, and financial capital are fully mobile a comprehensive income or profits tax should not be assigned to the state and local levels because it is necessary for such a taxation to be optimal so that a jurisdiction should be able to tax all income of its residents in the other jurisdictions. This is certainly not a realistic case. Beyond this, taxation of wage income tends to reduce this tax base less than the taxation of capital income and it could thus be more easily taxed at the state or even local level unless tax authorities cooperate and exchange information about taxpayers' incomes. And even profits taxes can be levied at the state or local levels if investment is specific to the locality such that a firm cannot easily relocate. The latter is particularly the case for not-in-my-back-yard (NIMBY) firms like waste incinerators or nuclear power plants. These firms have difficulties finding a location and assigning local jurisdictions the power to tax their profits gives these communities an incentive to provide such firms with a location.

Following from this reasoning is another rule for tax assignment: Progressive taxation, designed to secure redistributional objectives, should be assigned to the central level. A progressive income tax should thus be a federal tax. Moreover, as the case of Alaska illustrates, a large natural resource tax base permits local jurisdictions to provide public services at a low tax price leading to an attraction of individuals and firms at an inefficient scale. On these grounds, a case for central taxation of natural resources may be made whereby the central natural resource tax may apply to an excess base only, while leaving the average base for subfederal use.

All in all, these basic considerations led Musgrave (1983) to present the following tax assignment to government levels: the local level should rely on property taxes and payroll taxes, the state level on a resident income tax, a consumption tax, and a natural resource tax, and the federal level on an integrated progressive income tax and a natural resource tax for large natural resource bases. All government levels should additionally rely on fees and user charges as far as public services are attributable to particular users or certain groups of users. This possibility is probably reduced from the local to the federal level. According to Musgrave, corporate source income ideally would be included in the integrated base of the federal income tax. These propositions become substantially more complicated, if interjurisdictional tax agreements providing for tax credits or deductibility are considered. Federal tax deductibility of state and local taxes, for example, may mainly serve taxpayers with higher income and is thus regressive.

Tax Assignment in Some OECD Countries

A first look at real tax systems in OECD countries quickly reveals that tax assignment is not necessarily Musgravian (Pola et al., 1996; Pommerehne and Ress, 1996). The US seem to come closest to those rules of tax assignment. The US states are prohibited by the US constitution from levying taxes on imports or exports but otherwise they may adopt any type of tax that does not egregiously discriminate against citizens of other states. US states have a lot of freedom in defining their tax bases, in setting tax rates, and in offering tax abatements to induce businesses to locate within their state. Finally, the states grant tax authority to differing degrees to local jurisdictions, too. While there are only minimal restrictions on state power to tax in the US, the federal level nevertheless relies mainly on the individual income and corporate income taxes, the states on sales taxes and natural resource taxes, and the most important source of revenue at the US local level is the property tax. Although state tax revenue from individual income and corporate income taxes is nonnegligible, it is only about one fifth of the respective federal revenue. Such a favorable judgment about the US tax system is, however, only justified at a first glance. According to Feldstein and Metcalf (1987), for example, the federal tax deductibility of personal income tax liabilities led many states to rely more heavily on deductible personal income taxes than on other type of revenue.

Apart from the US, for example, in Canada and Australia and particularly in Europe, the assignment of taxes to the state and local levels differs considerably from the Musgravian model and varies widely across countries. In Canada, personal and corporate income taxes are the most important revenue sources of the federal level. The most visible of taxes in Canada, the personal income tax, is, however, also the most important revenue source of the provinces. On the one hand, there are fairly significant income tax rate differences between provinces. On the other hand, arrangements between the Canadian federal and provincial governments on sharing the bases for the personal and corporate income taxes have a long history going back at least to the Second World War. There is also a large variation in sales tax rates from Newfoundland to Alberta as the second important revenue source of the provinces. Canadian local jurisdictions, like those in the US, mainly rely on property taxes.

In Australia, the federal government exclusively levies taxes on personal and company income, sales taxes, and (nearly exclusively) excise taxes. The bulk of a state's tax revenues are derived from payroll taxes, stamp duties, and associated taxes on financial transactions, and so called franchise (i.e., business license) fees on alcohol, tobacco, and petroleum products that are not so much differing from excise taxes as well as lots of smaller revenue sources. Local governments, on the other hand, derive their revenues almost entirely from property taxes. Australian states also obtain revenue from the central government on the basis of a revenue sharing arrangement.

The Australian tax system is not as different from the German and Austrian system of state and local taxation. In particular Germany has established an extensive revenue sharing arrangement of personal and corporate income and value added taxes as the most important taxes accounting for about three quarters of total tax revenue. These are really shared taxes in the sense that German state governments decide on them together with the federal government. The federal government has at its own discretion only the gasoline tax and a surcharge on income taxes while the states have no power to tax. Local government relies on property taxes and local business taxes.

The less federalist European countries usually have taxing authority at the local level. In the UK, however, there is not only no regional or state level of government, but local authorities basically have not much power to tax, only some power in determining tax rates of the local property tax on real property. The formerly existing local business tax in the UK was abolished by the 'Thatcher' administration which cut the contributions of local taxes to local revenue sharply after the unsuccessful attempt to introduce the poll tax in the 1980s. There have been some changes in the UK at the end of the 1990s to establish regional authorities in Scotland, Wales, and Northern Ireland providing at least the Scottish government with some power to tax. The UK thus appears to be following the trend in Europe to a more decentralized government structure with a power to tax for subfederal governments as well.

Since the 1970s, systems of regional government have been given an enhanced role in taxation in France, Italy, and Spain. In France, there are three levels of subnational government: the local level with about 36 000 cities and communities, about 100 départements and 22 regions. Since 1986, the importance of these subnational governments has increased. All three levels have the possibility to levy a property tax on real property (land and construction built on it), a local business tax ('*taxe*

professionelle') and something similar to a residents' income tax ('*taxe d'habitation*'). All three taxes are subject to central regulation, but nevertheless there is a nonnegligible variation in tax rates.

In Belgium, there is a movement toward fiscal federalism since it is agreed that the sales and property taxes will become exclusive taxes for the regional and local levels. Apart from smaller taxes, the three Belgian regions additionally can levy a supplementary rate on the personal income tax which may be positive, a surcharge, or negative, a tax reduction. Although there is some regulation of the local and regional power to tax income, the variation of rates is considerable. In contrast to that, local governments in the Netherlands can only levy property taxes.

An interesting pattern of local taxation can be observed in the Nordic countries. Basically, Denmark, Finland, Norway, and Sweden are unitary countries with only two government levels. According to the studies in Rattsø (1998), local governments have considerable power to tax in Denmark and Finland, less so in Sweden, and only to a limited extent in Norway. In Denmark and Finland, local governments can rely on taxes on property and personal income (nearly) without restrictions for setting tax rates accompanied by a considerable variation. In Sweden, local taxation consists mainly of personal income taxes with less variation in rates due to the central regulation of local governments. In Norway, most tax revenue originates from income and wealth taxes shared with the central government giving local authorities taxing power only within a narrow band. Since 1979, all local governments apply the maximum rate. The property tax is not available to all local governments, but is restricted to urban areas and certain facilities (notably power plants). In addition, local property tax rates are also limited to a narrow band.

In Switzerland, states (cantons) have the basic power to tax personal and corporate income as well as capital. The local jurisdictions can levy a surcharge on cantonal direct taxes and raise their own property taxes. The central government relies mainly on indirect (proportional) taxes, the value added tax, and specific consumption taxes like the mineral oil tax. It can also rely on a source tax on income from interest. There is, finally, a small but highly progressive federal income tax, which, together with revenue from the source tax on interest income, amounted to 34% of total federal tax revenue in 1995, while the cantons and municipalities rely on income and property taxes to about 50% of their total revenue and 95% of their tax revenue. In addition, personal and corporate income taxes in Switzerland vary considerably between the cantons. Taking the value of the (weighted) average for Switzerland as 100, the index of the tax burden of personal income and property taxes varies from 55.6 in the canton of Zug to 135.8 in Fribourg in 1995, while the index of corporate income and capital taxes varied from 57.6 again in Zug to 145.6 in Nidwalden.

As the overview of these selected OECD countries in Table 1 indicates, there is no clear picture of which kinds of taxes are assigned to the state and local levels. Local jurisdictions regularly levy property taxes as well as fees and user charges. Some power to tax personal income, at least labor income, is attributed to state and local governments in the US, Canada, France, Belgium, the Nordic countries, and Switzerland. In some cases, for example, Germany, France, and Switzerland, there exist even local business taxes in the discretion of subfederal jurisdictions. But on the whole, the assignment of taxes does not follow along Musgravian lines and there is a considerable variation in federal regulation of subfederal taxing power.

Table 1 State and local tax assignment in selected OECD countries

Country	*States*	*Local authorities*
USA	Income tax Sales tax Natural resource tax	Property tax Sales tax
Canada	Personal and corporate income tax Sales tax	Property tax
Australia	Payroll taxes Stamp duties Franchise fees	Property taxes
Germany	No taxing power	Property tax Business tax
UK	No state level	Property tax
France	Property tax Business tax Residents' income tax	Property tax Business tax Residents' income tax
Belgium	Personal income tax surcharge Property tax	Personal income tax surcharge Property tax
Switzerland	Personal and corporate income tax Inheritance tax Wealth tax	Personal and corporate income tax surcharge Property tax
Norway	No state level	Personal income tax Property tax
Denmark	No state level	Personal income tax Property tax
Musgravian 'optimal' assignment	Residents' income tax Consumption tax Natural resource tax	Property taxes Payroll taxes

The Political Economy of State and Local Taxation

Given these differences in tax assignment to state and local authorities, the question arises which institutional and political factors explain the tax structure in different countries. An early contribution as to the choice of taxation in a political economy framework originates from Schneider and Pommerehne (1980). They develop a model of Australian tax and expenditure structure along with a model of selfish government behavior assuming that the re-election constraint is not always binding. In choosing among tax instruments, a government in power is only urged to follow the preferences of a majority of voters if an election approaches and the re-election constraint is binding due to low government popularity. Between elections, the government can follow its ideological preferences. This modeling of government behavior proved to be clearly superior compared to the traditional models of government behavior in ex-post predictions of important variables (government spending, GDP, etc.). In contrast, Hettich and Winer (1999) assume that the governing party or coalition always maximizes the expected votes which by themselves depend on the

consequences of policies for the economic welfare of voters. In making fiscal choices, political parties thus take into account economic, political, and administrative factors that determine the nature of electoral support and opposition associated with alternative ways of taxing. The authors present empirical evidence on the reliance on income taxation and income tax structure of the US states in 1985 and 1986 supporting their hypotheses.

Inman (1989) finds that redistributive concerns strongly influenced the decision of the 41 largest US cities between 1961 and 1986 to rely on property taxes, sales taxes, or user charges. The higher the demand of local voters for redistributive services, the less city governments rely on fees and user charges as well as sales taxes and the more on property taxes. Hunter and Nelson (1989) present evidence for the impact of interest groups on the local revenue structure. The higher the share of wealthy homeowners in local jurisdictions in Louisiana, the lower the share of property tax revenue and the higher the share of charges.

Besides vote-maximizing behavior of politicians and interest-group influence for redistribution in their favor, tax competition is a third factor determining the structure of taxation. However, the expected impact is ambiguous. On the one hand, tax competition for mobile capital and workers may lead to a convergence of tax rates to a low level. On the other hand, tax competition may lead to increases in tax rates if a state's geographic neighbors follow suit when it raises its tax rates. Such behavior might occur due to yardstick competition between states and local jurisdictions (Besley and Case, 1995). Due to their incomplete political information, voters evaluate the fiscal performance of representatives in their jurisdiction by comparing it to the fiscal performance of neighboring jurisdictions. If a state's neighbor increases tax rates, this state has an increased possibility to raise its taxes as well. Arkansas State Senator Doug Brandon once said: "We do everything everyone else does."

Finally, the structure of state and local taxation, like federal taxation, is influenced by the degree of fiscal illusion among taxpayers. The more complex a tax system, the more incorrect voters' perceptions about their true tax burden and thus their tax resistance, the more easily representatives can increase taxes in order to finance new spending. Pommerehne and Schneider (1978) present evidence for Swiss local jurisdictions that the extent of fiscal illusion attributed to the complexity of the tax system is less pronounced, the more voters can determine taxes and spending directly in fiscal referenda. Moreover, Matsusaka (1995) finds that US states which allow for the use of initiatives in their constitutions rely more on fees and user charges than on broad based taxes increasing the visibility of contributions to the public sector and the equivalence between public services and tax prices.

Concluding Remarks

Although a comprehensive assessment is still too early, state and local taxation, appears to be the outcome of political decisions shaped by constitutional provisions and influenced by economic and administrative restrictions. Voters, representatives, bureaucrats, and interest groups deciding upon taxation under the decision-making provisions of their constitutions and taking into account the mobility of tax bases and the accompanied tax competition and tax exporting determine to what extent state and local jurisdictions rely on property, income and sales taxes, or on user charges. The differences in these political, institutional, and economic factors explain why there are so many differences among countries in their reliance on tax sources at the state and local levels.

Abstract

The conceptual couple 'state/(civil) society' is a product of the protracted effort through which, starting with the Enlightment, a few generations of European intellectuals sought to characterize the advance of modernization. The juxtaposition of 'state' to '(civil) society' emphasizes the growing differentiation between, on the one hand, the structures and events directly connected with public authority, with the constitution and management of the polity, and on the other the structures and events which individuals generate as they pursue their private interests, express their emotions, acquire and exercise their capacity for judgment. Some institutional outcomes of this process can be still be recognized, according to many authors, in the shape and dynamics of contemporary societies.

An Unsettled Distinction

Speaking of a 'juxtaposition' between two concepts suggests that they lie on the same plane and are unproblematically complementary to one another. But this is not the only relation in which those concepts have stood to one another. In an earlier relation, the two concepts, instead, were closely overlapped. In a philosophical and juridical vocabulary that lasts between Aristotle and Kant, the expression 'civil society' designates a condition in which humans have left the state of nature by bringing about, and subjecting themselves to, political authority; one wrote of *societas civilis SIVE res publica*. Here, what made a society civil was the very fact of its being policed and governed.

Hegel (1953) breaks with this fusion of the two concepts in the *Philosophy of Right* of 1821. The civil society is understood as the set of individuals engaged in the competitive pursuit of their private interests (chiefly economic). The state is understood as an institutional site where identified collective interests – such as the increase in the state's security, or the maintenance of the public order – are pursued through expressly political activities.

But this juxtaposition is loaded with tensions, and Hegel presents conceptual entities – the family, the corporation, or the 'police' (which here means: the administration) – intended to mediate those tensions. Further, the juxtaposition may be perceived as a contrast between state and society, leading thinkers to take sides with the one or the other. Hegel himself opts for the state, but already Lorenz von Stein, who places the paired concepts state/society at the center of his main work, resolutely opts for society.

In a sense, so does Karl Marx, who like Hegel views civil society as the locus of the formation and confrontation of private interests of an economic nature. However, he endows it with a powerful, self-sustaining dynamic, grounded on means and relations of production, with respect to which the state itself loses the creative, autonomous power to drive historical development Hegel attributed to it.

Even in the course of the twentieth century, some authors prioritize one of two concepts and subsume under it the other. Oliver Williamson's (1975) theory of markets and hierarchies, for instance, posits economic exchange as the primordial social relation, and derives from 'market failures' the emergence of hierarchical, command-based relations, and thus of organizations. Implicitly, also in this view society, conceived in the first instance as the locus of market relations, precedes and in a sense justifies the state (if one sees in it a particularly significant organization). This priority of society, naturally, imposes tight limitations on what the state can and should do (see Karlson, 1993).

Such arguments imply that state/society is not a proper dichotomy, for one concept can be made to encompass and posit the other instead of accepting it as its peer. But there are also arguments to the effect not that one concept is sufficient, rather that more than two are needed.

Thus, one may object to the Hegelian/Marxian reduction of the civil society to the political economy or the market, and suggest for it an alternative referent. A model of a social realm focused on intellectual pursuits, and constituted and regulated without political mediation and power relations, can be found in the eighteenth century *Imperium Litterarum*, the international cosmopolis of *savants* and literati. Or one may seek to comprise within civil society the phenomena of culture and religion, or the institutions concerned with play, emotions, aesthetic expression, and other inter-individual relations not reducible to exchange. The market itself may either be made to adjust itself to the presence, under the conceptual umbrella of 'civil society,' of these new and rather different referents, or may be relocated to a third realm all of its own, as if to acknowledge its peculiarly powerful and demanding dynamic.

For instance, according to Cohen and Arato (1992), in advanced societies there are three fundamental institutional complexes – the state, the market, and civil society. The latter is conceived primarily as the site not of competition between private interests, rather of the formation of collective identities, of solidarity, of the formation and transformation of institutions by means of social movements. In this perspective, *tertium datur*. *Politics and Markets* (Lindblom, 1977) do not exhaust the social space.

Historical Roots of the Distinction

One reason why, at the purely conceptual level, the relations between the two terms are so unsettled, may be that 'state' and '(civil) society' should not be conceived as universal categories.

Whether we conceive them as juxtaposed or counterposed to one another, both expressions refer to historically unique ways of establishing and regulating both political and economic processes (and sociocultural ones, if a tripartition is accepted as more plausible).

The state/society distinction presupposes, and profoundly modifies, arrangements which had emerged in various European countries in the late Middle Ages, and which are often characterized by the German expression *Ständestaat* (literally, 'state of the estates'). But the expression is potentially misleading, for it may lead one to think of its referent as a 'state' in the modern sense of the term.

To avoid this misunderstanding the Austrian historian Otto Brunner (1968) has proposed replacing that expression with that of *ständische Gesellschaft*. By this is meant a context where constituted estates, through arrangements partly traditional partly agreed, take an active part in the government of a territory. However they do so chiefly in the exercise of their own privileges, not on a mandate from the central government; and in those privileges political aspects are tightly fused with both economic ones and with status ones, relating to honor and rank. Their activities of government are differentiated, but not as articulations of an overriding political function, rather on the basis of each estate's claims and responsibilities.

Furthermore, typically the component units of each estate are not individuals, but collective entities with a pronounced hierarchical structure. The dominant unit is the 'house,' understood as the seat and patrimony of an aristocratic dynasty. "The lord of the house (*Hausherr*), at the same time that he performed the function, which today we consider private in nature, of head of the family, also exercised an authentic political power (jurisdictional, administrative, representative) over the members of the house subjected to him," which tended to include the bulk of the local rural population (Schiera, 1983). Furthermore, each 'house' tended to be also a fortified place, an assemblage of autonomous military resources, which the members of the family (again, including the rural dependants) would employ at the behest and under the command of the lord. In that capacity the house normally took part in the ruler's military undertakings; but equally could also protect the house's rights, arms in hand, from encroachments by other houses, including the ruler's own.

Finally, the typical house constituted an *oikos*, which is/was the seat of a complex plurality of activities intended to make it economically self-sufficient, as much as possible without recourse to exchange. The monitoring and organization of those activities (including, critically, the periodic delivery to the lord's household of unpaid produce and labor by the rural dependants) engaged the lord's faculties of jurisdiction and coercion.

The Crisis of the Staendische Gesellschaft

The 'decline and fall' of these arrangements was caused by a critical aspect of state formation, the gathering at the center of a country of the faculties and facilities of organized violence, culminating, according to Max Weber's well known formula, in a monopoly of legitimate violence. Exactly because the aristocratic houses originally possessed an autonomous military capacity, that process, when it does not dissolve them outright, turns them into subordinate components of an unchallengeable public order, centered on the sovereign, their councils, standing army, and fiscal, administrative and judicial apparatus. The political autonomy of the houses, and thus of the estates they collectively constitute, is lost. The sovereign's superiority, while it does not suppress the houses' internal hierarchical arrangements (including, of course, 'patriarchy') relativizes them, flattens them. Seen from the summit of sovereign power even the most exalted members of the realm begin to appear relatively similar to one another, relatively powerless.

At the same time that centralized political activities become the prerogative of a sovereign power that performs them in a more unitary and rational manner, economic activities become decentralized. An increasing number of subjects decide what goods and services to produce, in what ways, by interacting according to their own interests and capacities. The provision for the needs of the individuals depends increasingly on their capacity to enter into traffics with one another on the market.

In the countryside, commercialization reduces the part played in the totality of the economic process both by the aristocratic patrimonies and by the traditional rural units constituted by villages, which had shared the aristocrats' preference for self-sufficiency and their hostility to the market. It also diminishes the significance of city-based productive units regulated by guilds, which typically contrasted the market's tendency toward innovation and the free combination and recombination of resources.

To sum up: while state-building dissolves the *staendische Gesellschaft* by taking from it tasks, resources, and legitimacy pertaining to the political sphere, the advance of an economy based on traffics pushes into the market the units let loose by that dissolution. Against an expressly political organization with a strong vertical gradient, concerned with all relations grounded on *imperium*, there stands an open-ended set of increasingly numerous social units which, in the pursuit each of its own interest, establish with one another horizontal, or apparently horizontal relations.

The Political Prerequisites of the Civil Society

This can only take place, however, insofar as the process of state building reflects two peculiar principles: first, the political center takes on all expressly political concerns and resources but only those; second, it acknowledges the existence of private subjects who, while excluded from the political sphere, act autonomously in others. In both ways, political power expressly limits itself, through complex and delicate institutional arrangements: for instance, the progressive denial of political and juridical significance to the religious interests of individuals, or the acknowledgment and guarantee of private property and of contract.

Heinrich Popitz (1986) highlights the historical rarity of such arrangements: "Only rarely has it been possible even just to pose the question of how to constrain institutionalized violence, in a systematic and effective manner. This has only

taken place with the Greek *polis*, republican Rome, a few city-states, and the constitutional state of the modern era. The answers have been surprisingly similar: the principle of the primacy of the law and of the equality of all before the law (*isonomia*); the idea of setting boundaries to all legislation (basic rights), norms of competence (separation of powers, federalism), procedural norms (decisions to be taken by organs, their publicity, appeal to higher organs), norms concerning the distribution of political responsibilities (turn-taking, elections), public norms (freedom of opinion and of assembly)."

Within this small set of experiences of limited political power not all counterpose two realms we might call 'state' and '(civil) society.' For instance, in the Greek polis individuals exist chiefly as soldiers and citizens, and the private dimension of their life is little valued and expressed. Only vis-à-vis the modern constitutional state does (civil) society emerge, through the processes indicated above.

In many other civilizations the tendency of political power to aggrandize itself, to possess itself of all resources (beginning with land and labor power) suppresses all autonomy of the society, and may even reduce all individuals to subjects or slaves. In the modern West, by acknowledging and protecting private property in productive resources, the political center allows at least some subjects to stand against it as autonomous units. This, according to North and Thomas (1973), greatly favors the advance of the division of labor and the enlargement of the traffic economy. But it has also distinctive political effects, best perceived *a contrario* in the 'decline and fall' of empires which fail to acknowledge and protect property rights (Eisenstadt, 1969).

The significance of private property has two implications. First, it justifies to an extent the Hegelian/Marxian understanding of civil society primarily as the site of traffics. Second, it entails that the civil society should not be envisaged as a 'flat' space, harboring no power relations; for private property, especially in the means of production, engenders a power difference between those who do and those who do not possess it. The state/society difference does not mean that power is institutionalized only in the former, but that the latter is structured (among other things) by power relations of its own, foremost among which are those established by property.

State and Society in the Twentieth Century

The complex interactions between the power forms that lie on each side of the divide shape, to a large extent, the dynamics of modern societies. In the twentieth century the prevailing trend could be called 'statism,' for it saw a considerable enlargement of the scope of state action. In totalitarian systems, this trend suppressed all institutional limitations upon that action, and threatened the existence itself of society as a separate realm. In other systems, it pushed back considerably the boundaries of that realm, but this in response also to demands originating from it. For instance, economically underprivileged strata sought to maximize the import of citizenship and to reduce that of their market position; many economically powerful groups sought the state's assistance in securing their profits and stabilizing or correcting the market itself, which for various reasons had lost its self-equilibrating capacity. A further component of the trend consisted in the strategies of groups (sections of the 'political class,' public employees, members of the so-called 'new professions') whose livelihood and whose opportunities for a greater sway on policy depended on an expansive definition of the state's role.

Whatever its protagonists, in non totalitarian countries that definition was much assisted by the existence of a 'public sphere' and by the institutionalization of adversary politics, which gave voice to broader social strata, and found its most recurrent theme in the respective scope of the state and the market. Political parties played the central role in this dynamic, sometimes opposing but more often supporting the 'statist' trend. This expressed itself, among other things, in the formation of bodies and agencies that sat astride the traditional divide between the public and the private realm – as with the Italian *para-stato* or the British *quango*.

In the last decades of the twentieth century the trend was challenged by social forces expressing themselves politically through conservative and/or right-wing parties. These sought to at least slow down 'statism,' and proclaimed the superior rationality of the market, which in their discourse, but to an extent also in practice, reasserted itself as the chief, if not the only institutional site of the civil society. This late revisitation of the economy-centered, Hegelian/Marxian conception of the civil society acknowledges that in contemporary society also human potentialities and social processes – of a cultural, communicative, symbolic, apparent noneconomic nature – which other formulations treat as a *tertium* with respect to both state and market, are in fact targeted and controlled to a large extent by great concentrations of economic power. This is achieved through new material and social technologies, and subjected to the logic of accumulation, which is increasingly focused on informational and financial resources. Mostly those technologies are developed and operate transnationally, and thus increasingly escape the reach of the political competences and facilities vested in the states. This lends a new edge to the attempt to reduce, after decades of 'statism,' the significance of public and political action, and to enhance that of the market.

Also the end of the Cold War operated in that sense, for it reduced the necessity for strong political/military tutelage of the capitalist order. It also loosened the constraints of the Keynesian compact which the dominant strata had previously made with the lower orders and implemented largely through state action.

Both dominant trends – the explicit or implicit reduction of civil society to the market, and the slogan prevalent in the advanced countries at the end of the twentieth century: market, *si*, state, *no* – are potentially worrisome. The market itself remains the site of the formation and interaction between large economic forces, endowed with great power; and these are increasingly operating in a transnational space. In contrast the state – still wedded to the territory – can no longer perform even its most traditional functions, jurisdiction and police, let alone those functions of guidance and intervention in the economic realm it had increasingly claimed during most of the twentieth century.

These recent phenomena compromise the institutional tenability of the couple state/society nearly as much as it had been threatened, earlier, by the totalitarian state or by central

economic planning. A seriously dis-empowered state cannot establish and monitor an authentic civil society complementary to itself. In this sense, the Aristotelian and medieval vision according to which only a politically organized society can truly call itself 'civil,' deserves to be revisited.

Abstract

Modern statehood is a mode of political organization of 'society' in which the state is the primary agent charged with building its representation. The nation has become the preferred form for this representation, law, the principal means used to anticipate the conduct of its subjects (citizens) and develop normative frameworks (policies) to direct change, and democracy, the dominant form of self-representation. The scope of the state now goes beyond traditional activities such as war and the production of laws that regulate the exercise of power over territoriality and commerce to extend to the generation of forms of subjectivity in people.

Modern statehood is a mode of political organization of 'society' in which the state is the primary agent charged with building the representation of society aware of itself and in harmony with itself. Nation-states have become the preferred mode by which all of the earth's polities organize people and territory into formally comparable and sovereign governing units. The scope of the state now goes beyond traditional activities such as war and the production of laws that regulate the exercise of power over territoriality and commerce; it also generates new forms of subjectivity in people. Anthropologists initially observed this expansion of the state by studying the elimination, transformation, or preservation of indigenous peoples, tribes, peasants, clans, and kinship systems through the creation of encompassing, though also exclusionary, national forms of belonging. One major state activity that anthropologists have identified has been the deployment of ethnographic modes of defining and categorizing human populations and of systematizing knowledge about them, especially in colonial states. Hence, the science of anthropology has followed closely and defined its objects in terms of state projects, alternately supportive and oppositional: itemizing culture traits and social organizations of discrete peoples, tracing efforts at internal and external colonization, mapping the settling and resettling of territory, and tracking diasporic populations and global trade routes.

The 'state' refers to a form of polity that links people and territory in 'societies' and thereby demarcates itself from other states. Although archaeologists date states back to ancient Egypt and Mesopotamia (about 2500 BC), this article deals only with the anthropological aspects of the modern state. It examines the implications of linking people to territory on subject formation; the administration of populations and their cultures; and on the practices of religiosity, kinship, and commerce, as well as on anthropology itself.

The Concept of Modern Statehood

Modern statehood is a mode of political organization of society in which the state is the primary agent charged with building the representation of society aware of itself and in harmony with itself. Today, the nation is the preferred form this representation assumes. It is always an idealization and always in tension with the actual forms of group organization and their heterogeneous, agonistic compositions. Modern law is the principal means by which the state attempts to create this harmony, an ideal state in which there is a coincidence between behavior and rules and where the state can anticipate the conduct of its subjects (citizens) and develop normative frameworks (policies) to direct change (Nader, 1990).

States are only one of many rule-making institutions with administrative capacities. International and supranational bodies also increasingly make law. And while states largely retain for themselves the power of legitimate enforcement, corporations, religions, nongovernmental organizations (NGOs), and other non-state actors are equally organized and rely on other sources of power to circumvent or control state law. In most parts of the contemporary world, however, states remain the institution with the most effective ideological and institutional apparatus, also recognized by other states, to claim to represent the entire people within a particular territorial jurisdiction.

Statehood became the central principle asserted in international law in 1648, with the signing of the Treaty of Westphalia ending the 30 years of war in North–Central Europe. Driven by industrial capitalism as a superior mode of production and accumulation, the state expanded its functions beyond the conduct of war, the administration of justice, and the regulation of commerce, to massive projects in the colonization of populations in the Americas, Asia, Africa, and the mid-East (Dirks, 1993; Stoler, 1995). Western European states, in particular, formulated projects of external and internal colonization, and they began to usurp religious authority's control over the definitions of transcendence, the bodies of their subjects, and the institutionalization of their life courses.

Initially employed as a political program in the French Revolution and subsequently written into the United Nations Charter, the nation form grew out of transformed empires and tribes during the process of European state formation (Tilly, 1990). It also dissolved a feudal model of society by means of cultivation of behaviors based in part on class emulation and conflict (Elias, 1982). At the same time, in a process of reciprocal copying, states in the Americas also emulated the nation form. This transformation of diverse peoples into unified nations appropriated local discourses of consanguinity and affinity and, in turn, was propped onto

and often reconstructed local kinship. Unification of nations was rarely accomplished without intermittent purges or other kinds of homogenizing processes. From the late fifteenth century to the early seventeenth century, all Western European states engaged, with often-disastrous economic consequences, in variant forms of ethnoreligious 'cleansing,' leading to population resettlement and the formation of victim groups.

In the twentieth century, national consolidations and the creation of new types of victim groups reached new heights, especially with the advent of fascist and racist ideologies originating in Europe and also employed elsewhere (Lefort, 1986). The peace treaties concluding World War I introduced into Eastern and Southern Europe the two conditions of West European nation-states – homogeneity of population and rootedness in the soil. In Eastern Europe, the implementation of these principles was largely elided during the Cold War, with the establishment of socialist states based on universal brotherhood and allied with the Soviet Union – a bloc that dissolved following the so-called velvet revolutions of 1989. Western European states emerged weakened from World War II and were unable to resist independence movements in their colonized states, primarily in Africa and Asia. These postcolonial states in turn nearly universally adopted the nation form to integrate diverse groups within territorial boundaries already drawn, arbitrarily, by European states. Nation-states have since become the mode by which all of the earth's polities are organized into formally comparable and sovereign governing units. Appropriation of the nation form effectively broadened the scope of the state to include the planned change of culture, variously defined, and the generation of forms of subjectivity in populations (Borneman, 1992).

Subject Formation through Linking Territory to People

The 1933 Montevideo Convention defined the criteria for statehood as having (1) a permanent population, (2) a defined territory, (3) government, and (4) the capacity to enter into relations with other states (Article 1, League of Nations Treaty Series No. 881) – with only the first two criteria consistently upheld. Between 1945 and 2011, the number of states recognized by international law as sovereign members of the United Nations increased from 51 to 193, with two nonmember states (the Holy See and Switzerland) and a few countries with sovereignty disputes. Defining statehood this way has numerous effects on subject formation. First, it produces pressures to unify ethnically mixed and territorially dispersed populations by centralizing legal and education systems and standardizing the life course. States uniformize by means of both bureaucratic technologies (the use of, e.g., interviews, surveys, and maps) and psychological appeals to the 'shared' symbolic universes they create (through the standardization of grammars and linguistic use, and the shaping of experience in ritual events and everyday routines). Second, it creates populations with mixed loyalties, settlers, or migrants who live in a place among peoples separate from the place and peoples with whom they primarily identify. Third, it generates categories of automatic exclusion (e.g., resident stateless peoples, resident internal 'minorities,' nonresident external others), which are then used frequently to justify war against external or internal enemies. Fourth, the dependence of modern political representation on territorial attachment reinforces identifications with territory and the desire for statehood. These identifications exacerbate territorial conflicts and often lead to wars between potential antagonists who tend to receive international recognition only when their disagreements are articulated in terms of border violations.

Despite the ubiquity of the nation-state, different historical experiences of populations have produced a variety of ways of classifying states, some corresponding to intent of the ruler, others to the relation of ruler to ruled, and still others to their cultural form. The twentieth-century conflict between 'socialist states' and 'liberal democracies' uniformized neither the state form nor the experience of citizenship, as local cultures had enduring influences on actual political forms and relations. Other factors, such as relations with colonial powers or unfriendly neighbors, independence or separatist movements, or dependent economic relations also strongly influenced national cohesion and state functioning, leading to increasing awareness that what some analysts label 'failed states.' In accounting for this variety of state forms and the historical conditions of their production, anthropologists have focused on the organization of public authority and forms of domestic control. The historian Foucault (1977, 1978) and the political scientist Anderson (1983) have inspired much recent scholarship.

The powers unleashed by science since the Enlightenment have generated what Foucault calls 'rituals of truth,' including disciplinary technologies that refigure space and the arts of governance charged with producing society and 'culture' as objects of knowledge and identification. Moreover, the deployment of new procedures of power in the nineteenth century transformed state authority from a sovereign's ability to 'take life or let live' (to order or require someone's death) to an investment in administering life by means of disciplining the body and regulating populations. States, Foucault argues, institutionalize particular cultural forms through projects of reform, education, development, incarceration, war, welfare, and family planning, along with the use of scientific techniques such as surveys, census, questionnaires, actuarial tables, economic forecasting, spatial mapping, case studies, and bureaucratic interviews. Anderson focuses on the historical conditions in which the 'imagined community' of the nation comes into being and achieves global currency, particularly in its relation to states following the collapse of empires. One of these conditions, print capitalism, enables advances in techniques of memory and collective narration through the proliferation of historicist myths and standardized accounts of experiences of national belonging across space and irrespective of local temporalities.

Because modern governing necessitates delineating a population and a territory, rulers invariably deploy ethnographic assumptions about how to define a people. As well, through laws and policies, states produce and circulate information about belonging (through families, schools, and the media); positively and negatively sanction prescriptive and proscriptive behaviors (about sexuality, gender, age, race, ethnicity, and work); and build libraries, monuments, and museums to display particular interpretations of the nation. In sum, modern

states are distinctive in that they produce both laws and people; they not only administer and regulate already existing cultural patterns but also produce new domains of objects and forms of subjectivity.

The Discipline of Anthropology and the State

Early anthropological work on the state, especially among archaeologists, was inspired above all by Friedrich Engels's study of the origin of the state and its relation to private property, Lewis Henry Morgan's evolutionary scheme, and Sir Henry Maine's theory of the progressive movement from status to contract in the development of state law (Service, 1975). Fieldwork-based anthropologists, inspired by Bronislaw Malinowski and Franz Boas, did not initially theorize the state or the nation, although their research was most frequently among indigenous peoples, tribes, peasants, and clans who were either in conflictual relations with states or involved in a process elimination, accommodation, transformation, or preservation in response to state challenges to their territory and resources.

The discipline of anthropology has closely followed and defined its objects in dialogue with state projects, alternately supportive and oppositional: itemizing culture traits and social organizations of 'discrete' peoples; devising evolutionary schemes; tracing efforts at internal and external colonization; mapping the settling and resettling of territory and the transformation of property; and tracking diasporic populations, cultural diffusion, and global trade routes (Moore, 1986). One major state activity that anthropologists have identified has been the deployment of ethnographic modes of defining and categorizing human populations and of systematizing knowledge about them, especially in colonial states (Cohen, 1996; Ferguson, 1990; Pemberton, 1994; Scott, 1998).

By and large, however, anthropological questions have revolved around the production of the cultural or social organization or forms of exchange among people considered marginal or obstacles to state projects (Sahlins, 1981). Throughout the first part of the twentieth century, a preference for fieldwork in villages or small-scale communities not fully integrated into states or supranational exchanges also made states less of a focus to the subjects of anthropological research. Further, long-term observational fieldwork among ordinary people often requires a kind of intimate access that precludes relations with rulers or those in the inner circles of power. Anthropologists in this period, therefore, assumed an essential sociocultural opposition of the people to the state (Clastres, 1987). This claim seemed credible, if not ethically imperative, when, as in the early twentieth century, the objects of study were so-called primitives and indigenous peoples, victimized and threatened with extinction, frequently through state-supported genocide, or, alternatively, when the state was primarily a puppet of a colonial power. Nonetheless, the opposition is misleading, as groups victimized by the state nonetheless must, and increasingly do, appeal to states for protections and remedies. Also, the state often provides the most powerful modality for representation of group interests.

Anthropology has in the meantime become a global discipline of alterity, no longer restricted to questions of origin or to particular kinds of peoples or places. Also, the relation of indigenous people to states has changed considerably, with some states now even guaranteeing the 'preservation of indigenous cultures' and prioritizing 'native' rights over those of more recent settlers. Moreover, the United Nations along with some NGOs and a global tourist industry positively sanction states that protect and support what are called 'first peoples' – a movement that has reversed the trend toward extinction and strengthened the importance of claiming cultural authenticity or temporal priority of settlement.

In any case, the notion of 'kin-based' or 'acephalic' polities as a pre-evolutionary stage to a 'state-based' polity, or of the replacement of status by contract, has become a moot for ethnographic research as the entire planet is organized territorially by states mutually regulated through legal contracts and unevenly integrated by global market exchanges (Moore, 1978). Anthropologists, instead, now investigate the simultaneity of the organization of kinship and the state, of various stages of developmental narratives, and of status and contract. The interaction of people with states may be an unavoidable condition of modern life, but it is by no means unambiguous in outcomes or in the trajectory of change.

This interaction took three meta-narrative forms in the second half of the twentieth century: people living within the bipolar Cold War structure of socialist or communist states (planned economies, single-party rule, so-called Second World of totalitarian states) vs liberal states (free market economies, multiparty democracies, so-called First World) and a contested zone of people living in postcolonial states (mixed economies with diverse political forms liberated from empires, so-called Third World). Until the late 1970s, anthropologists had difficulty obtaining access to people within the totalitarian states, and in other parts of the world they devoted considerable research to reconstructing the precolonial state.

In the mid-1970s, a global trend toward democratization of authoritarian states began in Southern Europe; was advanced in Latin America and parts of Asia in the 1980s; and spread to sub-Saharan Africa, Eastern Europe, and the Soviet Union in the late 1980s and 1990s, making the relation of these peoples to transforming states a subject of anthropological research (Coronil, 1997; Verdery, 1996). In 2011, the same process of challenge and destabilization of authoritarian regimes began among Arab-speaking populations in the Middle East. In effect, the space of the Second World has disappeared and the spaces of the Third and First Worlds are mixed, existing within each other, though in radically uneven proportions.

Beginning in the 1980s, the liberal democracies engaged in market reforms – dubbed 'neoliberalism' – that deregulated the finance sectors as well as many kinds of trade relations and corporate activity, and opened internal economic and cultural relations to global markets (Greenhouse, 2010). The ideology that markets and the private sector are more efficient than states and the public sector received a large bonus by the collapse of the socialist states of East–Central Europe and the disintegration of the Soviet Union. The end of the Cold War divide into East and West blocs accelerated these global exchanges across territories and on a larger scale than

previously possible, suggesting not only a need for states to regulate them but also demonstrating the limits of national law and the inadequacies of existing regulatory agencies to do so. In response to these newly extended and often global markets, the national subject, known as 'citizen,' was increasingly reduced to the identity of a consumer, which has changed the imagination of the individual's relation to the social (Dunn, 2004).

Of note at the beginning of the twenty-first century is the distinctive tensions created by the global integration of financial markets, the loss of state sovereignty over national economies, the proliferation of ethnic affirmation within states, and the denationalization (privatization and outsourcing) of much military conflict. State accommodation to globalization often compromises national sovereignty, although this varies greatly depending on the state's size, wealth, location in the international system, and its domestic legitimacy. States are under increasing global pressures to refrain from protecting local cultural forms, which, even if unable to maintain some autonomy in the face of globalization, are nonetheless not uniformized by global markets, a fact apparent both in the local variations in 'society's' relation to the state, specifically to democratic form, and to the continued patterned diversity of cultures, expressed in everyday routines and rituals. At the same time, however, one of the effects of these tensions is a dramatic rise in inequality within groups and the pauperization of large parts of populations in all parts of the world.

The vast majority of states now call themselves democracies and, therefore, operate in a specific mode of ruling and employ specific devices of power and strategies of self-representation. As a mode of ruling, this entails the introduction of regularized elections; the creation of ruling majorities and minorities; the institutionalization of an opposition; and the strengthening of principles of accountability that circumscribe the exercise of power, usually embodied in principles of 'the rule of law' (Borneman, 1997). As a device of power, however, some of these same democratic modes of ruling, such as majority rule, lend themselves to degeneration into forms of despotism. A state is often as dependent on the externalization of negative others as on facilitating an internal dynamics of citizen formation. Practices of such externalization range from state-tolerated social discrimination to legal exclusion of refugees to war against neighbors. As a strategy of self-representation, each democracy requires not only internal assent but international recognition too, which it obtains only to the extent it is able to claim governance by 'rule of the people' and conformity to international norms and conventions. When states violate such norms and conventions, which they frequently do, they risk censure, sanctions, or other forms of international pressure. Such pressure often strengthens the hand of local groups against the state.

Anthropologists engaged in research requiring listening to others are often asked to advocate in the international arena for the people studied and thus engage with all three registers of democracy. Their research often takes positions on local political struggles. As experts on culture, anthropologists are frequently asked to use legal disputes knowledge obtained in fieldwork that is critical of state modes of rule or strategies self-representation (Good, 2007). Given the increasingly global nature of 'news' and accelerated information flows across state borders, local struggles about representation quickly enter international or supranational arenas, subjecting the state to pressure from authorities external to it and explicitly drawing attention to the ways in which it exercises sovereignty. Such global flows also challenge state sovereignty by bringing to the world's attention local and subregional actors and events that might be in opposition to dominant groups within a state.

The study of conflicts in democratizing states includes research on social and legal citizenship and on the relation of state policy to demands for representation and accountability. Along these lines, four basic contemporary conflicts about representation and states are observable: involving excluded people who want more social, economic, cultural, or legal inclusion into states in which they reside; diasporic people who want representation in both the place in which they reside and the place from which they are displaced; numerical minorities (usually represented as a culture or a 'nation') who do not have their own state but want one; and citizens or social movements that demand more and various kinds of accountability from their rulers.

Legitimacy and the Modern State

Although the conception and functions of the modern state keep changing, a state's legitimacy is always based both on some notion of the 'consent' of its own citizens to rule and on the recognition of other states. This was not the case when rule was justified without recourse to 'the people,' in other words, rule based on coercion alone, on principles of heredity or wealth, the ability to wage war and collect taxes, or the administration of justice. To obtain this consent and recognition, the state must usually go beyond Max Weber's famous dictum that its power rests on a monopoly on the legitimate use of violence.

In many parts of the world, the state no longer even pretends, in fact, to hold this monopoly on violence. In the last 30 years, most states have tended to outsource and privatize many security functions. Where the state has privatized or even dissolved its former functions, the most vulnerable citizens tend to suffer the most from the lack of any protections. Indeed, today weak or 'failed' states are just as likely to lead to violent conflict as were strong imperial states in the last several centuries. In many places, the state's own abuse of this supposed monopoly – through genocide, strategic terrorism, the suppression of dissent, cynical uses of war – has traumatic effects on its citizens, leading to repeated and delayed suffering of past events. Increasingly, then, the anthropology of the state focuses on privatization, security, outsourcing, violence, vulnerability, and trauma (Masco, 2006).

Irrespective of whether they initiate or are victims of violence, states instrumentalize traumatic events, not only by building monuments to fallen heroes or soldiers but also through the construction of nationalist historiographies and support for a heritage industry that especially honors the idea of national sacrifice and organizes the process of mourning for losses after large-scale violence (Borneman, 2011). So long as

the state continues to draw legitimacy from principles of territorial sovereignty and peoplehood, it will be motivated to generate, exacerbate, and institutionalize differences with neighbors or neighboring states. Anthropologists are most focused on the effects of these conflicts and wars on the organization of populations and communities (Tambiah, 1992).

Also, the collapse of the Cold War's bipolar state system has resulted in the relatively unrestricted proliferation of arms, much of it driven by state-supported arms industries, and in a market for new and affordable technologies of death outside the control of states. Where the sources and agents of violence outside state control are increasing – a wide-ranging phenomena found, for example, in Colombia due to drug trafficking, in Sri Lanka and much of Africa due to civil war, and in the United States or Mexico due to poverty and class conflict – people employ private police forces and militias. States are also located ambiguously to many occasions of collective violence, such as genocide, at times instigating, at other times complicitous with local groups, and at others offering remedies (Ghassem-Fachandi, 2012).

Alternatively, many states now lend their militaries for 'peace-keeping' efforts in other countries organized by the United Nations, and still others, such as states within the European Union, are relinquishing military sovereignty to continental or transcontinental military alliances. There is also a growing body of legal doctrine – and an International Criminal Court established in 1999 in the Hague – that attempts to hold states accountable to their own norms and to international covenants and agreements on issues such as human rights, environmental and maritime law, and commercial law. The state's sovereignty and legitimacy, then, is not granted as natural but conferred by its citizens and by the recognition of other states and new international regimes.

Anthropologists now supplement the long history of linking the state to realization of the Idea of the people (Hegel), representation of the social (Durkheim), technical and bureaucratic rationality (Weber), or exploitation and class dominance (Marx), with an acknowledgment that most states still resort to magical practices and cultivate religiosity in order to legitimate rule (Taussig, 1997). State policies and edicts administered through 'law' often work through processes similar to magic: belief in the power of the utterance of the speaker, the performativity of speech, the linguistic rearticulation of group suffering and instrumentalization of memory, nationalistic narrativization of macro-political events, and ad hoc rationalization of failures and successes. Even in the domain of criminal law in what are considered the most rational of states – Germany or Sweden, for example – most crimes are never solved and most criminals go free. Yet, criminal law there still 'works' – that is, contributes to the legitimation of the state – largely through belief in the principles of justice that judicial inquiries, prosecutions, and trials efficaciously represent.

Likewise with respect to religion, states most successful in establishing a secular authority over local or world religions are those that recognize the significance of religiosity and incorporate religious traditions and symbolic forms into the secular rituals of political parties, elections, bureaucratic routines, and life course *rites de passage* (Gauchet, 1997; Herzfeld, 1992). Such practices are forms of group worship and they crystallize in patterns of national belonging when citizen and state narratives are brought into harmony. The struggle between the great world religions and the state to occupy and shape the symbolic forms of everyday life has not quieted, however. Secular narratives organizing life and death have proven incapable of replacing the power of myth and religious authority in accounting for the inexplicable or creating experiences of transcendence. Nonetheless, there has been a dispersion of the power over the control of religious expression, with religions also constantly subject to internal reform movements and no longer holding monopolies over local populations, and the state is one of many benefactors from this process.

In the last quarter of the twentieth century in most places of what is known as the First World, entertainment – especially involving sport and music – has emerged as the field dominating both the management of experiences of transcendence and of people's affective attachments and identifications. State rituals – especially electoral campaigns, legislative debates, memorialization and mourning ceremonies, and political speeches – have, therefore, increasingly incorporated models and techniques of authority drawn from entertainment. This leads to a fusion of actors ('personalities') in the two fields and an incorporation of magic and infusion of 'charisma' in the rationalized arena of state activity.

With the end of the Cold War, First World states increasingly structured their relations to new and Third World states by promoting NGOs. Acting in a negative symbiosis with the state, such NGOs also incorporate magic into their missionary projects of rational reform and economic and political development. In much of the world, they have become strong competitors to organized religion and to the state in providing care (welfare), in development projects, and promoting both local and global accountability in the exercise of power. Often, however, they serve primarily as instruments for the transfer of wealth or power between supranational elites.

Notwithstanding liberal mistrust of the modern state, reaffirmed by the horrors of totalitarian experiments, the nation-state form still provides the possibility for local control of people's own destinies in a manner impossible for prenational communities. Stateless people are indeed the most defenseless actors in the contemporary world. Hence, despite the wars, violent revolutions, and massive repressions of the nation-state, as the sociologist Lepsius (1988) argues, this form of polity has offered particular advantages to West European societies, including the institutionalization of peaceful conflict-solving through the rule of law, guarantees of individual freedom, the organization of interests through parliamentary democracies, and the integration of national economic development in the world economy. In each of these measures, authoritarian and totalitarian states elsewhere have been at a permanent disadvantage, incapable of recognizing the subjects they seek to control for whom they are and unable to organize power, except through coercion. Such states destroy sociality and build false representations of the people, thereby creating a basis for the illusion of society against state.

Abstract

Most social scientists would agree that the state consists of a set of ongoing institutions for social control and authoritative decision-making and implementation. Beyond this basic description, the concept of the state becomes multidimensional. The modern state emerged in Western Europe in the fifteenth–sixteenth centuries and became more firmly grounded in the seventeenth century. Its development is intimately linked to the political, economic, intellectual, and religious developments of the time. Theorists differ about the dynamic of the formation of the state and its consequences for domestic and international affairs over given historical periods. Because state formation and reformation is continuous, it is useful to examine how and why state formation took shape among the 'old' states, as well as how the 'new' postcolonial states address state formation in the light of contemporary exigencies. Today state formation and reformation vies with the forces for regional integration (Europe) and globalization, brought on by global commerce and the revolutions in communication and technology. State formation continues to be a work in progress.

A state consists of a set of institutions whose functions are social control and authoritative decision-making and implementation processes. In addition, modern states seek autonomy in their relations with other states. Beyond these very general criteria, the concept of the state quickly becomes multidimensional with respect to its historical development, its relevant legal considerations, and its theoretical debates. The institutions of a state are subject to conflict and disagreement over their structure and the role they play. Institutions change over time, and the changes both shape and reflect differing degrees of autonomy and strengths. In the twenty-first century there is considerable interest not only in the historical trajectory of state formation and the more proximate formation of new states – dozens of new states have been created in the second half of the twentieth century – but also in the concept of state capacity. Political scientists and political economists who measure and assess the strength and relative autonomy (sovereignty) of states in national and international arenas concern themselves with the proper role of states in the domestic and international political economy. States are in constant competition with other institutions such as intergovernmental institutions and for-profit and nonprofit institutions. Political scientists study and observe the role and function of each of these various national and international institutions. Not surprisingly, the proper role, the function, as well as the capacity of today's states has become a lively and contentious issue.

The Problematic of the State

Many prominent classical theorists studied state formation and the multifaceted issues surrounding the role and function of states. Theorists such as Machiavelli (*The Prince* 1988), Rousseau (*The Social Contract* 1987), Marx and Engels (*The Communist Manifesto* 1998), and Lenin (*State and Revolution* 1993) considered the formation and role of the state to be a theoretically interesting issue. More recent students of the formation of the modern state have focused their attention on such other topics as the absolutist states of Western Europe and states and revolution (Skocpol, 1979). Contemporary writers address issues such as the state and industrialization, nationalism, colonialism, and the formation of the state, in addition to many other topics concerned with communism and the postcommunist state. Other ongoing themes among students of state formation are the state and the economy, power and legitimacy, and the relationship of states to other states. Twenty-first century analysis of the forces of globalization and their impact on the state are also frequently discussed in the context of the historical evolution of state formation.

History of the State

The modern state is a Western European creation which emerged in the fifteenth and sixteenth centuries and became more firmly grounded in the seventeenth century. The modern state came into existence in the same time frame and in geographical locations that were the wellsprings of modern capitalism, modern science, and philosophy. Many scholars link the evolution of the modern state and Christianity in its Protestant form. It is generally agreed that the emergence of a new political form – the modern state – was intimately linked to the economic, intellectual, and religious developments of the time.

The first modern states to arise were Italy, the UK, France, and Spain. The principal technical tools of modern state building were the development of permanent bureaucracies and a standing army, but it was the availability of money that enabled rulers to acquire them. Once a ruler was able to control the professional bureaucracy and the army, the nobility of medieval times lost its political role and power. The principal producers of cash were the commercial and industrial middle class and the peasantry. By the late eighteenth and early nineteenth centuries the bourgeoisie was able to curtail and even

abolish the privileged status of the aristocracy and the authority of the monarch. The bourgeoisie acquired increasing control over the state. Their victory, signaled by the French Revolution, transformed the dynastic, state into the modern state. However, to define the modern state as 'bourgeois,' meaning 'civic' signifies the civil and legal equality of all subjects regardless of status by birth or occupation. The abolition of the old feudal privileges did not mean that the propertied and educated classes ceased to have privileges in the modern state. Modern theorists of state formation like Charles Tilly (Tilly, 1975) and many Marxist theorists like Miliband (1969), Poulantzes (1969), and Offe (1975) view the state as 'organized coercion' orchestrated by an elite. Other social scientists view the state as the arena of legitimate authority embodied in the rules of politics and in governmental leadership and policies.

Some thinkers, especially Marxists, tend to treat the state as an analytic construct by which to explain the modes of production, class relations, and societal struggles in general. Others, including Theda Skocpol (1979), argue that states are 'actual organizations' that control territories and peoples. Skocpol echoes the legal definition of a state much more closely than does Tilly for example, by pointing out that while the state is anchored in class-divided socio-economic structures it also needs to be seen as part of the international system.

As a practical matter, in order for a state to engage in international relations, other states need to recognize it as a fellow state. Modern sociologists call attention to the fact that a state is a human community that successfully claims the monopoly of legitimate use of physical force within a given territory. Whether a state is considered legitimate and on what basis its legitimacy is acquired and honored in the human community within the territorial boundaries of the state and in the large international community of fellow states, is to say the least, very historically and theoretically complex.

The Modern State

The modern state and the modern state system developed simultaneously. It required coercive capacity for the state to sustain itself both domestically and internationally. The state system of the nineteenth and twentieth centuries led to two world wars and the Cold War. These wars were significant in shaping contemporary states and the international system of states. However, contemporary concern and interest in the state is not confined to questions of the legitimacy of states or even their coercive capacity. At issue in the twenty-first century is the role of states as actors, competing with other actors, to determine what the ongoing proper role and function of a state ought to be with respect to its political, social, cultural, and economic obligations to its citizens.

State formation has never been simply a 'founding.' Quite the contrary, state formation is a process of formation and reformation based on the changing nature of societies within the state and the larger international system of states. The institutions and processes of a state and of states collectively are not static. To say that a state requires the capacity to carry out the proper functions of a state is a truism, but the capacities required at the turn of the twentieth century vary greatly from state capacities required at the turn of the twenty-first century. Furthermore, states compete with other national and international institutions. For example, states vie with interstate organizations, such as the European Union, the United Nations (UN), the World Trade Organization (WTO), and with nonprofit organizations such as Greenpeace and Oxfam, and for-profit corporations such as Microsoft and CNN. Financial capacity, knowledge capacity, monetary capacity, and even legal capacities of non-state actors all challenge state capacity. This is not to suggest that states have become defunct but merely that what it means to be a state today and what capacities a state is expected to possess by its citizens and in the larger community of states continues to go through a process of formation and reformation.

The Future of the State

As the twenty-first century begins there are more than 200 so-called sovereign states in the world. It is useful to think of contemporary states in their subgroups of differing state types: first, the 'old states,' such as the UK, France, Spain, the US, China, and Japan, which have developed reasonably stable nation states over the centuries. Some of these states, like the US for example, are multinational and multiethnic. Others, such as Japan, are more homogeneous. What these states have in common is a citizenry that views the national government as legitimate, and these states on the whole, share stable political economies. Second, there are the 'new' states. Many of these states, for example, most of the sub-Saharan African states and many states in Asia and the Middle East, emerged out of colonialism during the twentieth century. These new states tend to meet the legal criteria for statehood, yet many lack legitimacy as states in the eyes of their citizens. Most often such states are also multiethnic and have yet to achieve a sense of nationhood – a shared belief on the part of citizens that they belong to the nation-state. Some of these states, for example, Somalia or the Congo, are, at the beginning of the twenty-first century, in a state of civil conflict. States which are not able to carry out the basic function of a state, are frequently referred to as 'failed' states. Such states have the legal trappings of a state but the nation-state formation has broken down and the state's capacity to govern its territory has failed. In the category of failed or failing states are all those for which the historical process of state formation has not yet succeeded.

One may observe that the historical timeframe during which state formation takes place will determine both the internal and external factors which have a bearing on the process, as well as the outcome, of state formation. In the post-Cold War era for example, state formation and reformation – in the case of former communist states – is taking place at a time when the dominant paradigm is a democratic form of governance within the context of free market capitalism. Accordingly, state formation in the new states and postcommunist states, takes place in an international setting which exerts a distinctive global leverage on the type of state formation for which political and economic support and acknowledgement is rendered.

However, today state formation and the reformation of all states, not just new or failing states, takes place in the context of globalization. Globalization brings with it active participation

in the national and international life of states by nonstate actors and a new degree of interstate and inter-actor interdependence. Today global and regional institutions, along with states, participate in rule making, rule enforcing, knowledge creation, and in fields such as commerce, banking technologies, medicine, genetic engineering, and in defining the standards for human rights. The globalized world of the twenty-first century is reshaping the idea and the reality of the sovereign state. Yet states still are extremely important in the lives of most people and hence, state formation continues to be an important ongoing process, a process which is not merely a multifaceted historical process but a multidimensional work in progress.

Editor's Note

Since Gruhn's article was first published, the study of comparative state formation has exploded in a resurgence of the 'bringing the state back in' movement in the 1980s. A useful recent attempt to take stock of this growing literature is Vu, 2010. "State failure" is a key topic in this literature; see Eriksen, 2011. Another useful current source is Chase-Dunn and Inoue, 2012.

Abstract

The state is the world's dominant form of political organization and it reflects a territorial configuration that we tend to take for granted. The focus here is on its geographical dimensions and the article provides an overview of the origins of the state, and focuses on its three key and interconnected geographic dimensions – territory, boundaries, and sovereignty. Drawing on the work of key political geographers it indicates the complex intertwining of ideas of territory and sovereignty and highlights the evolving, contingent, and contested nature of state power and geographical control. While the state might be viewed as a territorial container, it is clear that some states exercise more effective and spatially extensive power than others. Theories of the state suggest it is much more than a mere spatial container, but rather a space in which dominant interests are pursued.

The state is currently the world's dominant form of political organization. Political maps of the world display this territorial configuration in a way that leads us to view it as 'natural' and this impression of solidity engenders a very state-centered view of the world. However, the state system is a political and geographic construct that displays considerable dynamism. In recent years the number of states has risen dramatically, consequent on state collapse (many associated with the fall of communism) and secessionist nationalism in various parts of the world. The changing spatial configuration of states, combined with various processes that suggest both a shifting role for the state and a possible diminution of its power and significance, furthers debates surrounding states, their origins, key features, role, and functions which this article endeavors to draw together.

Origins and Features of States

The focus here is on the modern state system, usually seen as deriving from the Treaty of Westphalia in 1648 which is generally held to have given rise to a territorial apportionment of land between European rulers, though the manner in which this evolved was far from uniform. States emerged through the construction of territories which could be measured and mapped, and could consequently be controlled, apportioned, and bordered (Elden, 2007). In considering how states have come into existence, geographers and others have been instrumental in developing theories of state formation and evolution. The German geographer Friedrich Ratzel likened the state to a living organism arguing that states would expand territorially outward in order to increase their size and power, swallowing smaller surrounding states in a struggle for space (Muir, 1997). In this way a form of social Darwinism is used to explain political processes in territorial terms. Population growth led to pressures which required the acquisition of more territory or extra living space – what Ratzel termed *lebensraum*. Another German geographer, Karl Haushofer, utilized and developed Ratzel's ideas of *lebensraum* prior to Hitler's use of the concept as a justification for German territorial expansion. These 'imperial' political geographers' ideas were bound up with the influence of both physical features, such as mountains and rivers, and human geographical considerations on politics and their role in affecting the strategies of states (Kearns, 2009). Other geographers explored the state in functionalist terms. Richard Hartshorne (1950) highlighted the competing centrifugal and centripetal forces to which states are seen to be subject. The first might include such things as regional inequalities, ethnic diversity, or language differences that might act as an incentive toward secession. Centripetal forces, on the other hand, serve to bind the state together and might include elements such as a common language or religious homogeneity.

While ideas of state evolution and internal coherence have some merit, they imply that states develop as part of some inevitable process. Although internal differences may have a significant bearing on the stability of a state, relative power balances between states need to be taken into account when attempting to understand the evolution of a world state system. Flint and Taylor (2007) utilize Wallerstein's world systems theory through which states are seen within the context of a broader global capitalist system. While it may be tempting to view the state as a set of institutions freely entered into, this is usually very far from the case and states tend to emerge out of violence and involve the imposition of control (Lefebvre, 1991). The creation, maintenance, and vitality of states have much to do with the balance of power between countries, rather than being simply reducible to internal characteristics. States emerge within a state system, not independently of each other.

The state is not a single unambiguous entity but a constellation of various elements and component parts. While precisely what it is may be hard to pin down, the modern state is dependent on three essential, closely entwined, and intrinsically geographical features: territory, boundaries, and sovereignty.

Territory

While the state is a political organization, it must have a territory, a portion of geographic space (land, air, water) over which it exercises power. Territory is a clear necessity for a state to exist and also provides the state with a seat of power and

a functional space in which to operate. States may also deploy internal territorializations in the form of regional units with varying degrees of devolution of power. At an elementary level we can say that states are territorial containers (though increasingly leaky ones) which have jurisdiction (or at least claim it) over politics, economy, society, and culture within their acknowledged geographic spaces (Taylor, 1994). However we need to be mindful of what Agnew (1994) has termed the 'territorial trap' whereby we effectively naturalize the state as a sovereign territorial entity.

It is easy to take territory for granted but, as Stuart Elden (2013) suggests, territory is more than simply land (or geographic space); our ideas of territory are dependent on ways of measuring and mapping it. Without developments in both cartography and geometrical means of areal calculation we would not think of territory in the ways we do. These advances brought with them legal and administrative developments and states emerged alongside bureaucratic systems that codified territorial control. Information gathering on the nature of the land, its features, and resources, as well as on people through censuses and related surveys, became essential components in state building. These led to a way of conceiving geographic space through which it could be owned, controlled, and administered. Mapping, which has generally been bound up with military, political, and economic imperatives, serves to make territory visible, accessible, and governable; as Elden (2013) argues, mapping is not just a tool of power, but a fundamental requirement of it. In addition the state serves to inculcate a sense of territorial or national identity with cartographic techniques appropriated for practical, symbolic, and propaganda purposes through which the state is rendered legible (Escolar, 2003; Scott, 1998). Territory itself results from the processes of state evolution and the mechanics of mapping and calculating space. In a sense then territory only exists because the state does. Territory is much more than a feature of the state in that it is both a facilitator and a consequence of state action (Brenner and Elden, 2009).

Boundaries

If states have control over designated territory, it follows that there must be recognized boundaries separating their own territory from that belonging to neighboring states. Clearly, these boundaries may be contested and may change or disappear over time. The rise of the bounded state as a political unit necessitated a concern with the drawing and redrawing of political borders and the formalization of territorial arrangements. Borders are places where the distinction between 'our' territory and that of others is made clear with the paraphernalia of the state very evident through flags flying at crossing points, passport checks, and police controls. Traditionally, political geographers have distinguished between 'natural' and 'artificial' boundaries. The former category encompasses naturally occurring phenomena, such as rivers and mountain ranges. The Rio Grande forms part of the border between the United States and Mexico, while the Mekong forms part of the boundary between Laos and Thailand. Lines of latitude such as the 38th parallel separating North and South Korea or the 49th parallel dividing the USA and Canada are examples of what are depicted as artificial borders. However, this binary distinction is somewhat misleading given that borders, whether utilizing naturally occurring features or not, are intrinsically artificial. States are human creations and, as a consequence of political decisions, some rivers become borders (or cease to be borders) while others do not. These sorts of boundary classifications are also predicated on an assumption that borders must exist, the only debate being over where the lines should be drawn. It is assumed that such things as ethnic or national identities are fixed and unproblematic and that territorial divisions separating them are 'natural,' desirable, and attainable (Fall, 2010).

Rather than a focus on boundary types, an exploration of the impact of borders and the nature of border disputes may be more worthwhile. Borders are constantly subject to change resulting from disputes over territory. These disagreements may relate to the precise location of the border or they may center on the very existence of a border in the first place. There are numerous examples of shifting borders across Europe including Germany's borders with most of its neighbors. Many borders are subject to ongoing dispute such as those between Venezuela and Guyana, and Surinam's borders with its various neighbors. In the Balkans the border between Macedonia and Kosovo has not been formally agreed and until recently was not an international border at all as both entities were part of Yugoslavia. The relative significance of certain borders changes over time. The Italy–Yugoslavia border was once of huge political import separating a European Union (EU) member state from communist Yugoslavia. Now Italy's border with Slovenia (one of Yugoslavia's successor states) is comparatively insignificant with relatively free movement between two EU members.

While the precise location of a border may give rise to conflict, in other instances its very existence is in dispute. The political conflict in Ireland revolves around the existence of the border between the Republic and the North. For Irish republicans, who wish to see a unified Ireland, the border is at the heart of the conflict, viewed as an imposed and artificial boundary whose removal is essential.

Borders are not just lines dividing territory; they are discursive constructs with important social as well as political ramifications (Paasi, 1999). Borders often cut through areas which are culturally homogenous but the creation and existence of formalized borders may lead to significant differences on opposite sides (Rumley and Minghi, 1991). In many respects, the imposition of a physical border can result in the emergence of a partitionist mentality contributing to the essentializing of national identity and accentuating linguistic and cultural divisions. Cold War boundaries, such as that between Austria and Hungary, had profound impacts on those living in close proximity to them (Meinhof, 2002). Political decisions taken in remote political centers can have dramatic effects on people who find their lives disrupted by shifting borders. The demise of the Soviet Union has had serious repercussions for certain groups such as the Lezghi in Dagestan (part of the Russian Federation) and Azerbaijan who, like others, now find themselves divided by an international boundary, leading to difficulties in maintaining a coherent identity (Birch, 2007).

In a myriad of ways, borders become elements within people's everyday lives and shape their day-to-day being. Their significance stretches from the global importance attaching to

the Berlin Wall in the later part of the twentieth century, through to the local but very real separation of people in cities such as Nogales and other towns and cities along the US–Mexico border. In addition, it is worth pointing out that for many the existence of state boundaries is, in some senses at least, largely meaningless. Many nomadic groups such as Bedouin people living in Iraq, Jordan, and neighboring states tend to ignore (or at least try to) what to them are meaningless lines on a map. Similarly, gypsies in many European countries may regard state borders as of no great significance in terms of identity, having no strong allegiance to the state in which they live. However, such groups may find themselves better treated in some states than in others, while borders often act as impediments on their ability to move freely between states. For those living in regions such as Kashmir or the Ferghana Valley in Central Asia, their lives may be heavily circumscribed by these imposed divisions of political space (Megoran, 2006).

Sovereignty

In addition to territory and the demarcation of bounded space, there is one vitally important additional feature which states must possess: sovereignty. This is a much debated concept but at its heart it refers to the authority of a state to rule over its territory and the people within its borders, without external interference. Sovereignty implies the existence of geographic space over which control is exerted and the emergence of ideas of sovereignty is intimately bound up with ways of conceiving territory (Elden, 2013). The global political map suggests a world of neatly demarcated sovereign spaces but, in reality, sovereignty is contingent, contested, and evolving. In an interstate system, international recognition becomes crucial and sovereignty is dependent on its acceptance by external parties. While a number of pseudostates exist (such as South Ossetia and Transnistria), they lack any widespread international recognition. The attainment of sovereignty depends not just on the nationalist aspiration for a separate state but also on the complexities of international relations (Harris, 2009).

Sovereignty disputes often derive from disagreements over where borders lie. Eritrea attained independence in 1993 following a protracted 30-year struggle to secede from Ethiopia. Both countries continue to claim sovereignty over stretches of disputed territory. The issues associated with enclaves and exclaves (areas belonging to a state but spatially separate from it, being embedded within the territory of another state) also bring with them questions of sovereignty. Although Nakhichivan is a landlocked entity lying between Armenia and Iran, it is neither independent nor a part of either of those states; instead it is an exclave of Azerbaijan. While the region of Nagorno-Karabakh lies entirely embedded within the territory of Azerbaijan (which technically retains sovereignty over it), with a predominantly Armenian population, it has been the center of a long-running dispute, declaring itself a republic in 1991 (though it lacks international recognition).

The US-led intervention in Afghanistan, Iraq, and elsewhere in recent years highlights the complexity of sovereignty in the contemporary era where global powers appear to exert significant and explicit power over territory well beyond their own state borders. Linked to this are more microlevel spaces where 'normal' rules of sovereignty appear to be suspended. The ambiguous territorial status of the US prison camp at Guantánamo Bay (in Cuba) has proven an effective excuse in allowing the indefinite detention without trial of its inmates who find themselves subject to interrogation by the US military authorities (Reid-Henry, 2007). This and other related practices render the relationships between territory and sovereignty ever more complex and blurred (Elden, 2009; Gregory, 2007).

Geographer John Agnew (2005) has attempted to move the sovereignty debate further by positing the idea of sovereignty regimes, referring to the capacity of states to exercise sovereignty. The effective sovereignty of many states is reduced through various processes and global flows, alongside the widening range of nonstate actors who might be seen to exert power across networks rather than over rigidly bordered territory. Part of the issue here is that sovereignty has never been as 'pure' or absolute as some might aver. Agnew identifies classic, imperialist, integrative, and globalist sovereignty regimes. The first might be seen as the 'traditional' view of the state operating within a bounded territorial space; the second alludes to situations where states are relatively weak and beholden to outside forces; the third refers to situations where there might be said to be a pooling of sovereignty though trans-state arrangements. (The EU is probably the most obvious example where absolute sovereignty is wielded neither by the overarching body nor by its constituent members, but rather reflects a form of pooled sovereignty operating hierarchically.) The globalist regime refers to ideas of trans-state sovereignty in an interconnected world but in which some states have considerably more influence than others and where their global reach extends well beyond their own boundaries (as exemplified by the example of the USA mentioned above). Sovereignty, for some, is contingent on adhering to particular ground rules laid out by the more powerful. External interventions by Western powers in a range of regions (including parts of the Middle East and Africa) serve to demonstrate that the territorial sovereignty of some weaker states may be seriously constrained. Some states display a willingness and ability to exert power well beyond their formal territorial boundaries (in pursuit of national strategic interests) while others (sometimes labeled 'failed' or 'rogue' states) become arenas for external intervention. The complex linkages between state sovereignty and territorial control lead to a consideration of effective sovereignty wielded by both states and a range of quasi-state actors and deployed in a variety of territorial contexts (Elden, 2009).

An additional element here is the processes associated with globalization (or linked together under that broad umbrella term), which are seen by many as signaling diminishing sovereignty for the territorial state. Borders are commonly depicted as increasingly porous in a world of transnational flows of people, goods, finance, and ideas. The emergence of regional economic alliances, epitomized by the evolution of blocs such as the EU, is heralded by some as the successor to the state system where boundaries are assumed to have diminishing significance. The financial crisis in recent years points to a considerably reduced ability of the state to maintain economic sovereignty. However, predictions of the demise of the state and the advent of a borderless world seem somewhat exaggerated. While a neoliberal economic orthodoxy (and its attendant crises) centered on trans-global economic flows seems to point toward the irrelevancy of borders, it

simultaneously utilizes and reconfigures them in attempts to increase the returns to capital (Harvey, 2010). In addition, there is the apparent paradox that while capital flows relatively freely across international frontiers, migrants (particularly those from poorer regions) continue to be faced with the intimidating bureaucratic and security paraphernalia of the state at border crossings. Ultimately sovereignty is relative, contingent, and never complete. It is always an ideal aimed toward, rather than a fully achieved condition.

Theorizing the State

In considering the role of the state it might be argued that it performs a number of key functions. It endeavors to regulate the 'national' economy, it provides public goods such as health and education, it maintains legal and other frameworks designed to guide and regulate its citizens' behavior, and it performs a policing and military function in defending its territory and its people against external aggression and internal threats. Viewed more broadly it can be suggested that the state ensures (or claims to ensure) representation, security, and welfare for its citizens. In many countries the period since the late 1970s has witnessed policies of denationalization whereby many state services have been privatized. This is part of a broader neoliberal economic agenda whereby the state's role is seen as a regulator of services (at best) rather than a provider. This has led to the 'hollowing out' of the state as private sector agents now carry out functions previously seen as the preserve of state agencies. In essence what has commonly been conceived of as the 'welfare state' has been eroded with a scalar shift to a heavier emphasis on voluntary and community responses to welfare provision. While 'rolling back the state' can be said to have had a definite effect in reducing the amount of direct contact people have with 'agents' of the state its influence remains pervasive. Even where service provision is by private companies these are usually subject to some form of regulation and the state continues to permeate our lives in a myriad of ways, evident in both our public and private dealings. Despite its seemingly reduced role the state continues to manage a highly regulated framework through which civil society is territorialized (Mann, 1984).

However, there is a need to consider the broader role of the state. Historically states have evolved from largely centralized entities with little popular participation through the development of electoral systems and gradual extensions of the franchise, thereby extending formal political engagement downward from an elite to include ever larger swathes of the populace. While it is tempting to see this as a form of natural evolution it is important to remember that most extensions of the democratic system have resulted from intense and often violent social and political struggle resulting in achievements such as voting rights for women, for example. At a simplistic level there is a tendency to think of the relationship between the state and its citizens as a freely entered into set of arrangements. While this is clearly not the case in authoritarian states, even in so-called liberal democracies there is a need to delve beneath the surface appearance of the state in order to more fully understand its role and functions.

From a pluralist perspective the state within liberal democracies is viewed as a neutral arbiter, above, and separate from, any vested interest. It is seen as an institution shaped according to the citizens' will, reflecting the basic democratic underpinnings of liberal democracy. Power emanates (via the electoral process) from the people who are deemed to be active participants in the processes of societal regulation. From this, it follows that governments merely act as the agents of the electorate. This classic liberal view of the state sees it as the guarantor of the rights of the individual. Pluralist states are seen as the polar opposites of totalitarian ones. Instead of one imposed view, there is a reconciliation of a variety of diverse views. Although at any one time a particular political party may hold power, and although they may represent a particular vested interest, the nature of the pluralist state is such as to ensure a system of checks and balances that safeguards the citizenry against abuses of power. In this way, an independent judiciary, media, and other elements are seen as integral components of the state apparatus. No one faction can have total control and states are seen as neutral and responsive to the various pressures within society. The state delivers the policies and services needed by society and is thus seen largely as a technical apparatus administering its territory for the benefit of its citizens rather than an overtly political entity. States may exhibit what appear to be healthy signs of democracy when judged on a procedural basis reflected in such things as elections and judicial processes. This leads to an assumption that the state is highly democratic and has not been 'captured' by any vested interest.

An alternative view is that, rather than the state being neutral, it acts instead in the interests of specific sections of society. It can be argued that specific elites tend to emerge whose perspectives hold more sway than others. Marxist theories of the state suggest a division along class lines with a basic distinction between a powerful class and a relatively powerless one and the state is seen as a mechanism which acts in defense of that structure. Far from being a neutral mediating party between various vested interests, the state acts in the interests of the prevailing capitalist system. Viewed this way, the state is not an independent structure standing apart from the rest of society, but is deeply embedded within socioeconomic relations (Held, 1989). It defends and protects the class structure by preserving existing power imbalances and it manages conflict so as to ensure the reproduction of the existing social and territorial order.

Despite outward appearances, states are not necessarily the open democracies they purport to be. The underrepresentation of certain strata in society within the arenas of power is one aspect of this (Miliband, 1969). More broadly, the state is constrained, being integrally embedded within a global capitalist system (Poulantzas, 1969). The collapse of communism in Eastern Europe witnessed the reconfiguring of political and state systems and the hurried implantation and global extension of a neoliberal economic regime. The current global financial crisis provides ample evidence of the nature of the state as a tool of capitalist regulation. The banking collapse of 2008 (consequent on a regime of limited state regulation) has been followed by government bailouts in various countries in order to prevent the total collapse of the banking system so that the architecture of the global financial system has remained

largely in place with the state–finance nexus as the 'central nervous system' of capitalist accumulation (Harvey, 2010). Rather than a disinterested and disembodied regulator, the state can be conceived of as an agent that reproduces society, culture, and polity. The administrative and territorial apparatus of the state and its seemingly banal bureaucratic procedures tend to mask its more overt political role, thereby serving to reproduce it (Sharma and Gupta, 2006).

When judged in more substantive terms the outcomes of the enactment of democracy may fall short of what the procedures suggest in terms of inequality and various forms of social and spatial exclusion (Bell and Staeheli, 2001). Despite this the state remains remarkably resilient. Mann (1984) argues that states wield despotic power (reliant on coercion) and infrastructural power (based on forms of negotiation). The first of these refers to institutions such as the police, army, and judiciary, which serve to keep people in line in a very obvious manner. The existence and power of this coercive apparatus is readily apparent in totalitarian states, yet it is no less important in liberal democracies, as evidenced periodically in the policing of protest marches and so on. However, of considerably more importance, especially in liberal democracies, is infrastructural power. In Gramscian terms there is a widely accepted set of 'common sense' propositions that are rarely questioned (1971). This acceptance of a particular way of viewing things is enabled through a variety of filters. Most obvious among these are education and the mass media. It is argued that these act as 'gatekeepers' of ideas, serving to permit discussion of some topics while largely ignoring others. In helping to shape public opinion, they can have a hugely conservative impact, protecting the state against potential opposition. The dominant ideas in society come to be seen as 'common sense,' constituting what Foucault (1980) referred to as 'regimes of truth,' and alternative ideas are portrayed as unreasonable, unrealistic, or unworkable. For example, the idea that cuts to welfare expenditure are necessary in terms of economic crises becomes a virtually unquestioned mantra. Other courses of action that might be pursued, such as cuts on military expenditure, are dismissed. While newspaper headlines target welfare fraud, tax avoidance by large multinational companies is considered almost 'natural' and inevitable.

From a Gramscian perspective, subtle ideological control is bolstered through systems of social welfare, provision of unemployment assistance, pensions, and other forms of support. Various spatial policies ostensibly designed to reduce regional inequalities might be seen as attempts to maintain the state's territorial hegemony. Notwithstanding periodic bouts of austerity and spending cuts, the state generally manages to deflect much opposition through the performance of its welfare functions, serving to 'buy off' the otherwise disaffected, and maintaining the political order. Another mechanism is the invoking of threats. Terrorist attacks can be mobilized as a justification for both foreign and domestic policies: of overseas military adventurism on the one hand, and increasing domestic surveillance and curtailment of civil liberties on the other.

Within this discussion, a note of caution is necessary. It is important to bear in mind that states are not unified, self-contained all-powerful units, but rather consist of a series of diverse and fragmented institutions, operating at and across a range of spatial scales, whose impacts on society are hugely variable (Smith, 2009). While the state obviously wields considerable power, spaces continue to be created in which opposition can be voiced. Increasingly diverse interpretations of citizenship point to the plethora of ways in which state hegemony continues to be challenged at local, national, and transnational scales (Yarwood, 2014). The utilization of public spaces for political protest of various guises is amply demonstrated in such diverse places as Tahrir Square in Cairo and Independence Square in Kiev.

Summary

This article has introduced the concept of the state as a political and geographic entity, it has outlined various theories of the origins of states, highlighted its key features, and cast light on the role and functions of the state in capitalist societies. The state is the world's most obvious territorial unit but it is a human creation resulting from the interplay of political processes. There is a need to be wary of not falling into what Agnew (1994) refers to as the 'territorial trap,' whereby states are assumed to be immutable entities. States are historically contingent, they are dynamic, and they reflect processes through which territory (and those living in that territory) is controlled. States do not just happen; they are created and reproduced, and occasionally subject to challenge. Through the appurtenances of the state we come to think in a territorial way. This state-centered approach reifies current political-territorial structures and portrays the state as a permanent and natural feature, they are historically contingent. States are more than mere spatial containers; they are dynamic entities, constantly reconfigured and reterritorialized through the complex interplay of internal and external forces.

Abstract

First, the fully developed power state of the nineteenth and twentieth centuries is defined against more loosely structured premodern kingdoms and empires. Next, a complex three-layer theory of state building is presented, and the corresponding growth of state power in European monarchies described. After an assessment of the role of political alternatives such as urban republics, the final development of the national, democratic, total welfare state between the French Revolution and the late twentieth century is analyzed. Finally, the multifaceted decline of state power since the 1970s is discussed together with its theoretical and practical consequences.

Introduction: Problems of Definition

At present, there are about 200 communities in the world that are considered sovereign nation-states, according to standards developed during European history. Officially, alternative political models no longer exist. Therefore, it seems reasonable to adopt the narrow definition of modern statehood created by German professors of law (Jellinek, 1959). According to them, a state is constituted by a homogeneous population inhabiting a contiguous territory under one single government that is characterized by complete independence from any outside authority (sovereignty) and holds the monopoly of jurisdiction and the legitimate use of violence internally. History has shown that this kind of state need not be a nation, and even less a constitutional democracy based on human rights. But today, most states claim to be nations under the rule of law and a formal constitution. Nevertheless, these are recent achievements and rather exceptional in world history.

History abounds with different kinds of political organization that may also be called 'states.' This is not quite correct from the historian's point of view, because in most European languages the term 'state' was originally used to designate social status or real estate. But between the seventeenth and nineteenth centuries, it became the name of a particular type of European political organization, achieving perfection during that same period. Before then, prestate communities can be roughly classified into (1) tribes without rulers, (2) chiefdoms, (3) city-states, and (4) empires (van Creveld, 1999). Historically as well as typologically, humankind was first organized in face-to-face communities, either acephalous societies without rulers based upon kin groups, or chiefdoms based upon force, wealth, and consequent social stratification. In addition, many chiefs were distinguished by religious qualities or supported by a privileged group of priests. All this is even truer of empires, which through religious ideology, a standing army, a kind of bureaucracy, and a tax system solved the problem of permanent control of large territories. This was a necessary precondition of future state building, but not the sufficient one, which was to be the achievement of some city-states of antiquity. Whereas everywhere else the distinction between ruler and owner of a polity did not exist or was at least blurred, in Greece and Rome for the first time citizens appointed certain persons to govern on behalf of the community and not for their own purposes, that is, not as rulers but as magistrates. These were the roots of the state as a transpersonal, abstract institution with an abstract legal personality (van Creveld, 1999). Therefore, the history of the state is first of all the history of the transformation of the loosely structured 'chiefdoms' of European aristocrats and 'empires' of European kings into modern states from the high Middle Ages until the nineteenth century.

Theory

European state formation was a multidimensional process, but most theories of state building are still one dimensional. Therefore, a multifactorial three-level theory of state building that combines (1) the microlevel of individuals and groups, (2) the mesolevel of the political system, and (3) the macrolevel of society is a more promising suggestion (Reinhard, 1992).

State building starts on the microlevel with the self-seeking lust for power of individuals, often with the competitive advantage of holding a kingship. Before the existence of the state as an abstract institution, the necessary transpersonal continuity was provided by the dynasty. Dynastic state building consisted in the elimination or at least control of the rival holders of autonomous power dating from the prestate phase of history – the nobility, the church, and urban and rural communities – in order to establish a monopoly of power. To succeed, dynasties needed the assistance of power elites that in their own interest made the growth of state power their own cause. In the long run, lawyers of bourgeois origin proved better qualified for that role than members of the church or the nobility because, in contrast to the latter, lawyers owed all their status and power to the service of monarchs.

Far-reaching change on the mesolevel of the political system resulted from successful exploitation of war, religion, and patriotism for the purpose of expanding dynastic power. The preexisting rivalry of European monarchs inevitably grew with their power, because it became essential to outstrip their neighbors, to grow at their expense, and to protect themselves against the same objectives in turn. Therefore, they needed continuously growing armies and ever-increasing quantities of money to pay them. In its decisive phase of growth, the modern state was a war state, which expanded its taxation, administrative, and coercive apparatus mainly to wage war. This

 http://dx.doi.org/10.1016/B978-0-08-097086-8.62098-6

resulted in a circular process, the coercion–extraction cycle (Finer, 1997), and finally in the internal and external monopoly of violence. Ultimately, only states wage war. Private wars, such as vendettas or feuds, or noble or popular revolts, were no longer legitimate under the powerful war and police state. 'Necessity' in the service of the common good served as the key argument to legitimate this growth of state power. But when the competing 'confessional' churches lost most of their autonomy to the state after the Protestant Reformation – the price to be paid for political protection – religion became an instrument of emotional identification of the subjects with their country. 'Catholic' and 'Bavarian,' 'Polish,' or 'Spanish' became almost synonymous, as did 'Protestant' and 'English,' 'Prussian,' or 'Swedish' on the other hand.

Essential contributions originated from the societal and cultural environment on the macrolevel. First of all, the geo-historical plurality of Europe was the incentive for the growth of state power through the coercion–extraction cycle. The result was a stable pluralism of internally strictly unitary states, an exceptional case worldwide. Universal empires never had a chance in Europe; the Holy Roman Empire of the Germans was at most a first among equals. But internal unity was not realized before the late eighteenth, the nineteenth, or in some cases even the twentieth century. For a long time, most monarchies were composed of several parts of unequal status such as Castile and Aragon or Polonia and Lithuania. And everywhere monarchs had to cope with a powerful system of autonomous local noble rule, on the one hand, with a countrywide network of partly autonomous urban and rural communities, on the other, once again European particularities. In addition, before the Reformation the church considered itself an independent community, in some respect even a state before the state. This singular European dualism of spiritual and temporal, combined with the equally singular political pluralism, turned out to be a precondition of political freedom, although neither church nor state, and neither noble landlords nor urban oligarchies, were in favor of any liberty except their own. Finally, the strong position of the church derived from its role as keeper of Latin culture. Roman law, to some extent transformed into the canon law of the church, directly and indirectly proved fundamental not only to monarchic state building but also to individual liberty and property.

The Age of Monarchy (Middle Ages to the Eighteenth Century)

European kings of the Middle Ages and the early modern period claimed to be emperors of their kingdoms, which is to say that, like the pope in the church, they held unrestricted power (*plenitudo potestatis*). For the first time in history, the competence of a king was defined by the French constitution of 1791. Before that date, royal power was limited only in the sense that there were some things a king could not do. The English king could not create statutory law or raise taxes without consent of the realm; the French king could not change the succession to the throne or give away parts of the crown domain. For the rest, every monarchy was 'absolute,' that is to say, the king's prerogative included everything necessary to fulfill his fundamental duties as fountain of justice and keeper of peace. In that sense, even Poland's 'republic of nobles' and England's parliamentary system were called 'absolute' by contemporaries. In Britain, where no written constitution defines powers, in theory the monarch today is still entitled to declare war and to conclude peace without consulting Parliament. In reality, however, since the later Middle Ages this was possible only if the necessary funds were raised with the help of representatives of the subjects. The monarchies of the European Ancien Régime were limited not so much by legal restraint as by small resources, traditional rules, and social conventions. Under these circumstances, it was decisive for the process of dynastic state formation that the crowns of Castile, England, and France became hereditary, whereas the Empire and to some extent Denmark, Sweden, Poland, and Hungary remained elective monarchies. Compared with the universal competence of the modern state, including the right to extend this competence at discretion, the prerogatives of early modern monarchs were extremely modest. State activity expanded when, during the early modern period, the so-called police ordinances (*Policeyordnungen*) started to cover new fields such as health and public welfare, moral order and communication, economic behavior, and labor relations. This was no longer mere jurisdiction, reactive government by rescript as in the Middle Ages, but an expanding administration actively interfering with larger and larger parts of its subjects' lives. But it was still not 'absolutism,' an anachronistic term of the nineteenth century that should be dropped (Henshall, 1992), because the kind of monarchy without any legal restriction that this term designates never existed except in Denmark from 1665 to 1834 and in Sweden for a few decades after 1693.

Similar to most monarchies of the world, European ones had a sacred character, practiced elaborate symbolic rituals, and were legitimized 'by the grace of God.' The coronation ceremony together with the coronation oath of the king and the corresponding oath of allegiance of the people were central in this respect. But there were varieties. In France, political rituals and ideology constituted a true 'royal religion' (*religion royale*), and court life with its palaces, ceremonies, and festivities became an all-embracing total work of art. Some of its elements recur in England and elsewhere, especially the ritual of the royal touch, when French and English monarchs touched hundreds of people suffering from scrofula, the tubercular 'royal disease' (*morbus regius*), to cure them. It is worth noting that kings practiced this ritual with particular intensity when their monarchy needed additional emotional support: Henry IV and Louis XIII of France after the religious civil wars, Elizabeth I of England because of her succession problems, and Charles II after the restoration. Other monarchies were more prosaic, including the Holy Roman Empire. And in spite of his politico-religious sanctuary, the Escorial, Philip II of Spain never wore a crown; there was not even a coronation ceremony in Castile. This was a way of demonstrating independence from the church, but even in France political sacrality implied royal control of the church and not the opposite.

Because of the church's monopoly of culture, Europe's early political discourse was theological. The state was considered a consequence of the fall of man. With the reception of Aristotle, natural man became a political being, a concept that was used to create an autonomous discourse of legitimation for the monarchy, erroneously, because 'political being' referred to the

face-to-face community of the city and not to the state. But from Dante Alighieri down to John Locke, political theory remained essentially a theory of monarchical state building, at most harmonizing limited monarchy with aristocracy and democracy into a mixed constitution, supposedly like the ancient Roman republic. Thomas Hobbes was the first to speak of the state instead of the monarchy, but this was not common practice before the eighteenth century, with Montesquieu and Jean-Jacques Rousseau.

This change coincided with the development of central institutions that under the impact of enlightened rationality became more effective. Administrators were no longer the king's personal servants but were transformed into professional officials of an abstract state, into modern civil servants (*Beamte*) as described by Max Weber. The early medieval prince was assisted in his governmental functions by members of his court and council (*curia regis*), and in his written legal work by a chancellor, often an ecclesiastic. Most central institutions of European monarchies were created by segmentation of that curia. The court was reduced to a mere household, and the chancery became a separate body. Professional supreme courts and treasuries were established. To produce political consensus and financial aid, an enlarged council of important subjects was created to become an assembly of estates or a parliament. What was left over of the ancient council was transformed from a multifunctional decision-making instrument such as the German aulic council (the Hofrat) into a differentiated system of governing bodies with a small group of confidants of the ruler at the core (the Privy Council, Geheimer Rat, Staatsrat, etc.). From the sixteenth to the eighteenth centuries, the conciliar principle of collegiality was common practice, to accumulate competence, to balance interests, to prevent disloyalty by mutual control, and to provide positions for as many members of the power elite as possible. Only a few very dedicated rulers such as Philip II of Spain, Louis XIV of France, and Frederic II of Prussia were still able to handle this complicated system of central government in person. Instead, many princes relied on a personal confidant as prime minister, such as Wolsey, Richelieu, or Olivares, or used the new office of a secretary of state for coordination. In England, parliamentary management was a central task of royal confidants. The development of modern cabinet government was the consequence.

In France, Castile, Rome, and elsewhere, many public offices were officially for sale, just another way to tap private accumulation in favor of public finance. The growth of state power was first of all a credit problem, because tax income had to be anticipated by credit to make the large sums of money that were necessary to wage war available on short term. Tax farming was another widespread technique used for that purpose. Direct taxes were based on the land, because movables and income were still not under administrative control. As usual, indirect taxes on mass consumption proved more comfortable, whereas the rich were involved as creditors. But credit was still the personal credit of a prince, not of the state as an institution. Therefore, repayment of loans was expected and interest rates were as high as risks. Under these circumstances, bankruptcy was the regular consequence of power policy until the Dutch and English invention of low-interest, long-term bonds with parliamentary guarantee, a decisive contribution to the further growth of the modern state.

Premodern Alternatives and Their Political Heritage

Traditionally, Europe respected man (and to some extent woman) as proprietor of his (her) person and goods. Therefore, in principle, taxation was possible only with the consent of the taxed or at least their lords and guardians. For this purpose, most princes created structurally similar assemblies of important subjects or representatives of corporations, such as cities, called assemblies of estates, beginning 1188 in León. By the seventeenth century, however, most princes were strong enough to raise taxes without consent and to ignore their estates. This decline of estates has been considered the very essence of 'absolutism' by former research. In contrast, we know today that to some extent estates remained alive in most countries (with the exception of Denmark) and princes still had to bargain with them. But only in England in the seventeenth century did conflicts with the Crown ended with victories of Parliament and the definite establishment of financial control by that body. This system, imitated in most European countries after the French Revolution, finally led to parliamentary government and democracy.

In contrast to other parts of the world, in European political culture the relationship between ruler and subjects was considered a contractual one, based on legal mutuality. In case of a supposed breach of contract by the ruler, subjects felt entitled to armed resistance, because their legitimate lord had degenerated into an illegitimate tyrant. Therefore, early modern discourse and practice of the right of resistance through a series of European revolutions laid the foundations of modern liberty and democracy.

In most countries, assemblies of estates were dominated by the nobility; as holders of local power, they were considered the true lords of the land. Not before the eighteenth century did the administrative institutions of the state start to penetrate this autonomous local power structure, and not before the nineteenth century was noble rule to a large extent replaced by public administration. But beside or below noble rule existed innumerable, more or less self-governing urban and rural communities, from independent republics like Venice, quasi-republics like German imperial towns, privileged English boroughs, down to villages of Polish serfs who were still entitled to regulate certain common affairs on their own. This is the 'Europe of a thousand republics,' the Europe of 'communalism' (Blickle, 2000), a world where members of face-to-face communities decided on their immediate concerns. These are the roots of European republicanism and of the tradition of European self-administration.

When assemblies of estates flourished, ecclesiastical power competing with princes was already declining. But the Roman church had been Europe's first state, with the pope as the first absolute monarch and the priest as the first nonhereditary professional public servant. The church practiced territoriality (*Flächenstaat*) at a time when empires were still mainly based upon personal dependency (*Personenverbandsstaat*). And the church established the rules of political religion, with the consequence that to the present day states remain transcendent entities in need of believers. In this sense, the state is the last church because European political culture is a culture of believers.

In contrast, professional law courts such as the French 'parlements' or the English 'common law and equity courts'

were not originally autonomous alternatives to state-building monarchies like aristocratic rule, communal self-government, or the church but creations of the expanding state power. Nevertheless, because of the loose structure of early modern polities giving room for the development of specific group identity and interests, these judges under certain conditions could transform themselves into opponents of their king's policy and initiate resistance or revolution, as happened in England and France in the seventeenth and eighteenth centuries. But in this way the principles of rule of law, of an independent judiciary, and even of judicial review of legislation were introduced into political culture.

In the end, however, the fully developed modern state replaced noble rule by a king's officials, reduced local self-administration to a commission of the central government, and established complete control of the churches and the legal apparatus. The principle of justice existing beyond, above, and before the state was largely replaced by the arbitrary use of the state's monopoly of legislation. But nevertheless the heritage of political alternatives remained alive: liberty and democracy, rule of law and independent judges, and the claim to self-government and to have a state one could believe in.

The Age of Equality (Nineteenth and Twentieth Centuries)

The modern European state, so far developed by state-building monarchies, reached maturity with the French Revolution and the political modernization of Europe that followed. Modernity means unity: unity of territory, people, government, sovereignty, and violence. The revolutionary process took the last step to modernity and replaced the hierarchy of orders and the plurality of privilege that had characterized the political society of the Ancien Régime with a society where stratification became a private distinction because politically all subjects were now equal before the state and its law. From now on, not families or corporations were the basic components of the state, but individuals. But mobilizing individuals emotionally in favor of the state into some kind of participation – not necessarily a democratic one – resulted in an ultimate increase of state power with incredible dimensions: the total state.

With the quasi-natural order of estates and corporations gone, the modern state of equal individuals needed a new organization. With the exception of Britain and Sweden (until 1975), this was provided from now on by a constitution. But in spite of the American and French models of 1787 and 1791, nineteenth-century European constitutions established rule of law but neither democracy nor fundamental rights. Their first purpose was equal integration, not equal participation. Most countries remained monarchies, but because monarchy was deprived of sacrality since the Enlightenment period, it lost unquestionable legitimacy. Step by step, monarchies were transformed into democratic republics or quasi-republics. But in most countries during the nineteenth century, democracy was still far away. This was not only informally as usual, but even legally: in their right to vote, all subjects were equal, but some were more equal than others (Orwell, 1945), mostly because of their wealth. In 1830, the following percentage of the total population was entitled to vote: in Austria, Denmark, Prussia, and Spain, 0%; France, 0.5%; Belgium, 1.1%; and Britain, 2.1%. In 1910, the numbers were as follows: in Denmark, 17%; Britain, 18%; Austria, Belgium, Germany, and Spain, 21–23%; and France, 29% (Reinhard, 1999).

Percentages in the 20s indicate universal suffrage of adult males. Down to the twentieth century, state building and politics remained almost exclusively a business for men. There were some outstanding queens and empresses in European history, such as Isabella of Castile, Elizabeth I of England, Christina of Sweden, Maria Theresa of Austria, Catherine II of Russia, and others. But some of these great women had their difficulties with male political culture. And there were no female ministers or officials. Even the enlightened philosopher Immanuel Kant considered women political nonentities because they lacked economic independence. After Wyoming (1869) and New Zealand (1893), female suffrage was introduced in Finland (1906); Austria, Germany, and Poland (1918); the United States (1920); Britain (1928); Spain (1931); France (1944); and Switzerland (1971). But in the late twentieth century, female heads of state or government, ministers, parliamentarians, and even female civil servants were still a minority.

Originally, human beings identify themselves mainly with their face-to-face community. 'Patria,' the land of the fathers, and 'Natio,' the community of birth, even during the early modern period quite often designated rather small territorial entities. However, through state building, people learned to apply them to their entire country. Finally, after the French Revolution, self-defined linguistic or cultural communities, peoples in search of a state, considered themselves nationalities, that is, nations to be. In contrast to ideology, nations are not natural but are invented entities. This does not, however, imply complete artificiality and arbitrariness. There is always some kind of basis in reality, such as common descent, language, religion, or territory. Most important is a common history and the consequent option for its continuity. Nationalism as a system of symbols constitutes a community as a nation, integrates its members, and defines the difference from other communities. For radical nationalists, the nation is the highest value and the ultimate source of meaning; nationalism becomes a religion and as such a way to tap the material and emotional resources of subjects, especially in war. Therefore, nation building became the final phase of European state building, whereas new states in Europe and worldwide tried to constitute themselves as nation-states right from their foundation.

Expanding political participation and emotional mobilization of subjects correspond to a further extension of government and of state power. A common denominator is a high degree of social discipline in the subject. Church and State had been working on this since the late Middle Age, but achieved this goal only in the nineteenth and twentieth centuries with the assistance of armies, schools, and factories (Weber, 1964). The citizens of a fully developed modern state enjoyed the legal protection of their person and property and some political participation. On the other hand, they were subject to three fundamental duties: compulsory school attendance, compulsory military service, and general liability to taxation. Based upon the fiction of the sovereignty of the people, the state apparatus was able to extend its competence at its own

discretion and to transform itself into a totalitarian system, as happened under the impact of nationalist, racist, and communist ideologies in the twentieth century. Some of them proclaimed the end of the state, but that proved impossible. In contrast, the totalitarian state turned out to be the final stage of development of the modern state. And, at a closer look, even the modern welfare state proves to be a soft variety of totalitarianism. Beginning with limited social security programs before World War I (1883–1889, the creation of an insurance system for workers in Germany), the welfare state exploded after World War II. Between 1950 and 1983, the Western European average of social security expenses rose from 9% of the Gross National Product to 25%. But total care for citizens means also total regulation of their lives. Even the neoliberal reaction is based upon large-scale government action in the service of a general economic and social policy; the goals, not methods, differ from those of former socialist welfare policy.

Six hundred years of European expansion made the modern European state the world's standard model of political organization. The colonial regimes of Spanish and British America established in the sixteenth and seventeenth centuries adopted premodern forms of European statehood and political culture. Therefore, most Latin American states remain authoritarian but weak states even today, whereas traditional self-government in a comparatively egalitarian society made the United States a successful nation, although it lacked certain traits of the modern state such as belief in the state as a value in itself, in bureaucratic centralism, in a strong professional army, and in an established church. During 1839–1935 Britain's white settler colonies became sovereign states, mostly combining the British and the US models, whereas in the nineteenth and early twentieth centuries East Asian and Muslim empires tried to transform themselves into modern states to cope with the weakness of their traditional regimes when confronted with the West, in the case of Japan with tremendous success. Finally, during several waves of decolonization after World War II, the lot of quite artificially created colonies became equally artificial nation-states. For the first time, a global community of international law and moderately effective international organizations such as the UN became reality. Quantitatively and qualitatively, the modern state reached its culminating point during the twentieth century.

The Disintegration of States and Possible New Forms of Political Life

In the last third of the twentieth century, the culmination of the modern state turned into decline. To begin with, most 'new' states worldwide suffer from serious shortcomings, such as lack of democracy and efficiency, general corruption, and political disintegration. The export of European state models was a success in only three specific constellations: (1) where it was accompanied with the export of European civil society and political culture, as in the cases of the US and the British dominions; (2) where it met a polity and society compatible with its own structure, as in the case of Japan; and (3) where colonial rule lasted long enough to create a Western-style civil society, as in the case of India. For the rest, the new states of the former colonial and the former communist worlds tend to lose their sovereignty internally to the para-statehood of old or new chiefdoms or ethnic communities, and externally to international organizations like the UN or the IMF. They become mere 'quasi-states' (Jackson, 1990). In addition, certain Muslim countries revise their option for secularity, which is an essential trait of the modern European state.

At the same time, European states were also, to some extent, disintegrating into 'tribes,' were losing sovereignty to 'chiefs,' pressure groups, and international organizations; and were no longer able to provide complete social security. As a consequence of totalitarianism and mass participation, the modern state turned self-destructive. The excesses of nationalism, racism, and communism destroyed the necessary faith in the state. Social discipline was questioned by the common desire of self-realization. New ethnic, regional, and social movements started to compete with the state for the loyalty of its subjects, some on the basis of democratic self-determination, and some with the use of violence. Withdrawal of loyalty favored an underground economy expanding at the expense of the tax and welfare systems. The necessity to win elections by bargaining with interest groups and by providing additional welfare benefits for the electorate ended in a debt trap with almost the whole budget allocated in advance. In some cases, an expanding public debt, once the basis of the growth of state power, led to a debt load exceeding national income. State bankruptcy could be avoided only by international intervention. In addition, economic globalization allows important taxpayers to move to less restrictive countries with lower wages and taxes. On the other hand, for economic and security reasons most states lose more and more of their sovereignty to international organization. Despite a common currency (the euro) established by 17 of its members between 1999 and 2002, the European Union has not yet become a federal state and suffers from deficient democracy and social policy. Nevertheless, common economic interest has released remarkable binding forces and still makes the union attractive for new members.

On the other hand, the right to declare and to wage war, once the very essence of sovereignty, has become obsolete. Only the United States is able to start wars at its convenience, and it does it to police certain parts of the globe in their present role of world hegemon. Instead of interstate wars and peace treaties, we have hundreds of 'low intensity conflicts' (van Creveld, 1991) that tend to respect neither noncombatant status nor national borders. International Muslim terrorism may in reality still be marginal, but after the attack on the World Trade Center on September 11, 2001 it is considered as a menace to state power.

Nevertheless, the national state is still there. But it has definitely lost the monopoly of power and policy. In power processes, it tends to become one competitor among others. Unity, the constituent principle of modernity and the monocratic polity, is being replaced by a postmodern plurality of multiple political units coordinated by the necessity to cooperate and not by state power. In this situation, it may no longer be adequate to speak of 'the state' in the essentialist sense of a stable unit but rather to liquefy terminology by employing instead the dynamic concepts of 'stateliness' (*Staatlichkeit*), which may differ in degree, and of 'the state as process' (Schuppert, 2010). Certainly, the new pluralism of political

constructs might end in chaos. But it might also prove to be a new way for humankind to seek the political pursuit of happiness.

Abstract

The formation of states changes the rules governing the behavior of the groups it comprises in ways not easily foreseen. The *emergence* of unanticipated behaviors is a characteristic that states share with other complex systems. These are systems in which there are levels of self-organization, and where agents at one level are the building blocks of the next. Such environments are increasingly referred to as *complex adaptive systems*. A change at one level alters the options for change at another, making it difficult to predict the behavior of individuals in constantly shifting environments and organizational formations. At each level, the agents adapt, they acquire new identities, and adjust their behaviors to new sets of rules and to the expected reactions of others. At each level, the constituents are likely to exhibit new behaviors, and how they adapt and act together to create the behavior of the whole is not easily reducible to the sum of the parts.

States as Complex Systems

States consist of government institutions, and rules, but if devising those institutions, rules, were the whole story, we would not be asking why long and costly efforts at building state institutions – those that enable citizens to perform complex collective tasks – often fail in developing regions. Traditional approaches to state formation emphasize the parts, institution, groups, or culture, but it is the relationship between the parts that gives rise to the collective behavior of the whole.

There are several key reasons why building state capacity involves more than drawing up a plan and then implementing it. A state is capable of performing complex tasks because of how its members interact with each other, and not because of how each member behaves separately. The greater part of the story concerns the transitions of behavior, expectations, and culture that occur when new institutions are introduced. They can form and be effective without being planned. State building refers to process through which a social system acquires new structures and behaviors that its individual components did not possess.

A state's behavior is not reducible even to the most exhaustive catalog of institutions or the rules of the game which includes according to Douglass North "formal rules, written laws, formal social conventions, informal rules of behavior, and shared beliefs about the world, laws a well as the means of enforcement" (North, 1990, pp. 3–4). The rules of interaction matter as much as the specifications of the component parts, and successful adaptations are contingent on other factors in the same environment. The way the component social networks and institutions are interconnected determines their behaviors over time. The behavior of one or more components is modified by the behavior of yet another. New behaviors and characteristics can emerge unintentionally, and even in direct contrast to the goals of those who contribute the resources and labor. Moreover, identical institutions set in a different social network will produce different outcomes; what succeeds in one environment may fail in another.

Even when very specific tasks are involved, such as organizing the central bank or managing the monetary system, no one-way or best practice to accomplish this task is applicable to all states. Managing health services or delivering education is even more dependent on local circumstances. Variations in social network structure will produce qualitatively different outcomes despite the existence of institutions that share a common design.

The formation of states changes the rules governing the behavior of the groups it comprises in ways not easily foreseen. *Emergence* and *interdependence* are two concepts that are critical to understanding the relationships between the parts and the environment that produce the collective behavior of the state. Emergence and interdependence are characteristics that states share with other complex systems. These are systems in which there are levels of self-organization, and where populations or institutions at one level are the building blocks of the next. Such environments are increasingly referred to as *complex adaptive systems*. A change at one level alters the options for change at another, making it difficult to predict the behavior of individuals in constantly shifting environments and organizational formations. At each level the agents adapt, they acquire new identities, and adjust their behaviors to new sets of rules and to the expected reactions of others. At each level, the constituents are likely to exhibit new behaviors, and how they adapt and act together to create the behavior of the whole is not easily reducible to the sum of the parts.

Emergence refers to any behavior that occurs between agents that contributes to a more complex behavior of the whole. A state is a nested hierarchy of interactive components. Lower or inner levels of organization combine into higher levels, i.e., groups of individuals form families, groups of families form neighborhoods, groups of neighborhoods form cities, and groups of cities form metropolitan regions, which connect to provinces. The social networks or institutions at one level are the building blocks of the next, but at each level of aggregation, the behavior of the whole shifts. None of these levels exhibit the identical behaviors characteristic of their individual components. Emergence is a collective property that arises from the relationship between the parts.

States do not exist in isolation from the larger systems in which they form a part, nor do they result solely from the accumulation of events in a local population. They are parts of the international system and acquire structure by being embedded into a larger systemic whole, and they interact with that broader system, even as their constituent parts interact with each other.

 http://dx.doi.org/10.1016/B978-0-08-097086-8.32149-3

Interdependence describes a state's relationship with its environment, both its natural and its human environment. Because of interdependence, cause and effect are not obviously related. For example, democratization, along with the concepts typically associated with modernization – individualism, tolerance, freedom of association, and free media – and modernity – urbanization, industrialization, and mass education – all occur in the context of a state (Gellner, 1983). However, process and structure are interdependent and are not readily separated. States are catalysts at the same time that they are outcomes of the processes they affect. Socioeconomic megaforces produce states at least as much as states have an influence on those forces. Direct institutional interventions usually have paradoxical outcomes because of socioeconomic interdependencies.

One consequence of the combined effects of emergence and interdependence is that relations among states and economic/political developmental processes within states show sensitivity to initial conditions and are subject to informational cascades. Another consequence is that some prominent metaphors for large-scale historical change are implausible and misleading such as modernization theory, uniqueness of the west, and the end of history. In terms of policy operations, both emergence and interdependence limit conventional approaches to centralizing authority, building institutional standards, or expanding state capacity.

The Great Discontinuity

What differentiates a state from a nonstate social collectives kinship-based community is the role of kin selection and reciprocal altruism. In nonstate communities, trust and cooperation occurs primarily among members of a society who carry the same genes or who interact repeatedly in the same environment. Kinship-based communities grant "selective advantage … to the altruistic interaction of individuals sharing part of the same genotype." (The definition of kin selection is from Mayr (2001).) The transfer of altruistic norms from families and kin groups to nonkin members is the essence of state making (Fukuyama, 2011).

The social capital that forms in kin-based or homogeneous local societies can thwart the formation of civic culture that state building requires. In its more general use, the term refers to political authority modeled on that of a father within a family. Patrimonialism refers to political recruitment on the basis of kin selection and reciprocal altruism among individuals sharing a common bloodline (Fukuyama, 2011). In this sense, patrimonialism can be considered the opposite of bureaucratic rule. Max Weber refers to patrimonial rule as it is projected beyond the family to an entire society or even nation. Both ancient and contemporary histories offer many examples of bureaucratic offices that are filled by a ruler's kin. A contemporary example of the power that patrimonial identification can have over an entire culture is the domination of Indian politics since independence in 1947 by the Gandhi family and that political incumbency at all levels of political representation depends on family connections.

Patrimonial rule is frequently associated with an additional obstacle to the effectiveness of the state: patronage networks, sometimes referred to as patron–client networks. They are a form of reciprocity based on dependence and inequality in which power brokers create a following by exploiting control over scarce resources, not only material wealth but also any resources that confer status or prestige. The patron gains power by delivering benefits selectively, according to the value of the loyalty that can be extracted from the recipient. These networks are most durable when the debts of the weaker partner can never be paid off or when the clients have limited channels of communication with the outside and depend on the patron for contact with other power brokers in the wider society. The extent of patronage networks was traditionally limited by the need to maintain face-to-face relationships, but modern political parties allow patronage webs to be woven across entire nations. The patron can be the traditional elite who are able to revive their moral authority by representing or protecting their dependent local clientele in national or subnational arenas.

Patronage networks incur significant transaction costs that divert resources from alternative uses. It limits networks of exchange to personal sources of information. Lacking a formal institutional structure relationship-based reciprocity results in fewer transactions and less stable outcomes than state-based norms. Modernization theory tended to assume that patron–clientelism was a residual, or vestigial, characteristic of the old order, but instead of being phased out by economic development, 'neo-patrimonial' regimes have arisen in which formal institutional structures must compete with informal networks. (Authority is personal and familial, modeled upon the mechanics of a household, which contrasts with the concept of a rational bureaucracy governed by formal rules where authority is delegated according to competence. Administrative hierarchies ensure that the private and official roles are clearly separated.) Many political parties in recently formed states function as patronage systems. Contemporary India offers numerous examples, beginning with the Indian Congress Party whose model of creating vote banks via patronage distribution has been copied. Many local political parties later emerged that cater to distinct clienteles by offering public services selectively. In this regard, the history of state building in India parallels that of Brazil, Mexico, and Turkey, as well as many other newly emerging democracies.

No society completely eliminates patrimonial tendencies; the psychological motivations of patrimonial reciprocity are very strong. Nevertheless, state order built upon patronage networks can easily regress once the leader is ousted. In Southeast Asia, once patrimonial leaders Ferdinand Marcos and Suharto were rumored to be ill, the asset values held by their patrons collapsed. Institutional regression is another more long-lasting consequence of patrimonialism to state formation. Once Marcos and Suharto were toppled or after Arab dictators Hosni Mubarak, Muammar Gadhafi, or Ali Abdullah Salah were ousted during the Arab spring, deinstitutionalization occurred. (Patrimonial democracies are less likely to regress when power changes, making them more stable than patrimonial autocracies.) The forfeiture of institutional assets each time power changes hands causes political routines and organization to regress as well. As a result, the gap between the quality of governance in state-based and nonstate societies grows larger.

Time Consistency and State Formation

When patrimonial systems of social authority circumvent loyalty to formal institutions, the result is likely to be 'time-inconsistent' preference functions for the entire society. (Time-consistent choices are those that are consistent with longer time horizons.) In such environments, people make poor choices wisely. They sacrifice the long term for immediate payoffs because the value of assets depends on the value of impermanent interpersonal relationships. Europe and China transitioned from patrimonial domination through different institutional channels. Imperial China had much higher levels of public provision than its neighbors because a rigorous exam system weakened kinship as a basis of administrative authority. The states of Western Europe that sharply separated lawmaking from the exercise of sovereignty afforded a far wider range of public goods than did the societies of Eastern Europe that remained under patrimonial domination.

All societies face a time-inconsistency dilemma when the leadership cannot precommit to rules over discretion. Two ways of making time-consistent behavior a social value are bureaucratic rationalism, or perhaps more broadly to establish public order on a rule-of-law foundation. Both of these strategies entail a compromise of discretion for the dominant coalition; both will eventually circumvent the patrimonial system and clash with hierarchies of birth and lineage.

Leaders who commit to the creation of a meritocratic bureaucracy or rule-bound system with an independent judiciary do so at the cost of sacrificing personal power. Yet without such an infrastructure in place, a state's behavior will not be time consistent. The players will know this. If resource holders have no expectation that a government will carry out its plans for the future, they will make only short-term plans. Such societies will have to forgo long-term payoffs in favor of actions that have only immediate payoffs. A reform program that can be undone by decree is only as good as the paper on which it is written. The time inconsistency of government actions does not disappear when a rule-based framework is established. But the risks to property of discretionary behavior are made more tractable, and this shifts the population's investment horizons toward the longer term.

Credible Commitments and Democratic Transition

The leaders of young democracies face a time-inconsistency dilemma if their promises and commitments are not institutionally credible (Kydland and Prescott, 1977). When the new leadership lacks the mechanisms of an effective bureaucracy or system of rules to make its promise credible, they must resort to patronage if only to stabilize their authority. If the leader calculates that the short-term gain of political survival is more important than the long-term gain of regime survival, then instead of providing the public goods needed to secure democracy in the long term, such as policy-driven political parties or state bureaucracies, a leader may allocate surplus revenues to prevent defection of those groups whose loyalty and resources are needed to prevent a crisis in the present. Voters and politicians in young democracies lack informational mechanisms to ensure that promises to policy performance are met. Voters may not even be able to observe if a policy promise is directed at them, and hence they cannot be expected to respond (Keefer and Vlaicu, 2007). The budgetary trade-off they make in favor of creating more private goods risks long-term stability; they may maximize their chances of staying in power at the risk of a volatile end.

Credible Commitment and Growth

The ability of a state to foster or hinder growth has much to do with its ability to project the assurance of credible rule enforcement. Citizens will be willing to make investments in the projects of nonkin in a rule-of-law system when the rights of all economic actors are heeded. The scope and scale of voluntary exchange will increase and an accelerated rate of capital accumulation will enable states to grow stronger by borrowing or taxing the holders of capital. But when economic advantages are ceded on the basis of prior social ties, or on political access, networks of exchange will be limited by dependence upon personal sources of information, the best plans of the best organizers will fail to materialize. Social responsibility and trust will be limited to the extent of kinship networks.

Strong but limited government has proven to be the most certain path to bind the hands of rulers to time-consistent policy options. The simple reason is the inadequacy of planning for directing the creation of a complex system. The complex tasks that economic development requires cannot be anticipated or performed with certainty by central design. The engineering of a highly complex system requires an evolutionary rather than a centrally planned approach. States are not built, they are grown.

Abstract

This article begins by defining 'civilization' and 'states' and tracing the intellectual history of these two concepts in Western thought. It then introduces the term 'agrarian state' as a less biased, more informative designation for these ancient societies. The key characteristics of agrarian states are described. For the economy, key characteristics include: intensive agriculture, taxes or tribute, craft specialization, long-distance trade, and (sometimes) markets. For social life, the key characterisitcs include social division by class, gender, and ethnicity; coercive institutions including law courts, police, and armies; and (sometimes) cities. For cultural life the key characteristics include: an elite ideology expressed in religious ritual, monumental architecture, and writing, and ideologies of resistance expressed in traditionalism, ethnicity, and revitalization movements. The article concludes with a discussion of theories for the rise of agrarian states (functionalist and conflict theories) and for the fall of agrarian states (external and internal causes).

Civilizations

'Civilization' has had two meanings in reference to ancient societies both of which require critical review. First, civilization has designated complex prehistoric cultures with productive economies, class stratification, and striking intellectual and artistic achievements. Civilization in this sense has contrasted with 'primitive' or 'tribal' societies i.e., societies with modest subsistence economies, egalitarian social relations, and less extravagant art and science. Civilizations have been equated with progress and cultural superiority, a view promoted by European elites of the early modern era. Using ideas of civilization and progress, these elites assumed the role of civilizing agents to legitimate their domination of the working class at home and colonial peoples abroad. Modern anthropologists reject narratives of civilization and progress, preferring less ethnocentric accounts of non-Western cultures. Anthropologists now use more neutral terms to refer to the complex cultures of the ancient world, calling them complex societies or archaic states.

Civilization has also referred to the enduring cultural traditions of the specific regions of the world. Distinctive cultural principles characterized large geographical areas of the world for long periods of time, outliving the expansion and collapse of individual polities. For example, the idea of cyclical time was a fundamental principle among the Olmec, Maya, and Aztec people of ancient Mesoamerica, and it is an idea that persists today among indigenous peoples in Mexico and Guatemala. While contemporary anthropologists recognize the persistence of such orienting concepts, they reject the possible inference that these long-lived ideas imply cultural stasis. In the past as in the present, old concepts were reinterpreted in the face of new situations. Nor do these enduring principles imply uncontested social harmony. People of different social standing might share a set of cultural principles, but still arrive at different conclusions regarding appropriate behavior.

States

State has been a more useful term for analyzing complex societies. States are powerful, specialized institutions for public decision-making and control. State government was the most important element of complex ancient societies. The state created a surplus economy that supported many of the other institutions characteristic of complex societies: infra-structural investments, administrative bureaucracies, full-time craft specialization, long distance trade, market exchange, law courts, armies, and priesthoods. Every archaic state had among its key institutions: (1) some form of surplus extraction e.g., corvée, tribute, or taxation; (2) a bureaucracy that supervised the upward flow of tribute payments and the downward flow of tribute demands, and (3) coercive institutions, including armies, law courts, and police, to ensure tribute payment.

Archaeologists once characterized archaic states as having relatively simple systems of class stratification: nobles and commoners, or tribute-receivers and tribute-payers. But more recently, archaeologists have emphasized the diversity of groups within the state, their complex interactions, and the state's chronic instability. Archaic states were constantly threatened by both internal and external forces. High-ranking nobles led factions that competed for positions of rule. Provincial leaders stood ready to declare their independence from state control. Lineages and ethnic groups resisted the state's appropriation of their collective assets. Households tried to evade the state's demands on their goods and labor. The history of states and civilizations is the history of strategy and counter-strategy deployed by oppositional groups, leading to the development of complex societies and their dissolution.

Key Characteristics of Archaic States – Economics

Economic activity in archaic states was guided by the principles of efficiency, security, and control. All economic actors took into account the efficiency (e.g., the cost:return ratio) of economic alternatives. But peasants and household-based craft specialists often sacrificed efficiency for security; that is, they avoided economic alternatives that placed their annual subsistence at risk. States, on the other hand, often sacrificed efficiency for control; that is, they organized some forms of production so as to monopolize output rather than to maximize returns. Peasants, too, were sometimes guided by their

desire for control; they were inclined to produce goods whose attributes (e.g., perishability) made state appropriation less likely.

Agricultural and Pastoral Systems

Archaic states were characterized by highly productive agricultural systems. The vast majority of these states were dependent upon agriculture augmented by some form of water-control, terracing, and/or fertilizer. Mexico is famous for its chinampas (raised fields), Peru for its terrace systems, Mesopotamia for its irrigation canals, and China for its rice paddies. Such systems enhanced both agricultural productivity and reliability.

At one time, archaeologists believed that states came into existence in order to construct and manage intensified agricultural systems as a response to the problem of population pressure (this is the 'hydraulic hypothesis' of state formation). But periods of state formation do not coincide with periods of population pressure, and the study of contemporary irrigation systems in tribal societies suggests that such systems can be built and managed without centralized forms of government.

States did have good reason to construct agricultural facilities. First, such systems provided income to the state. Agricultural facilities constructed with corvée labor represented prime agricultural land that the state could claim as its own without alienating existing property owners. Second, agricultural facilities attracted tax-paying settlers. Peasants were drawn to newly available, high quality land, and they were willing to pay for access to it. Third, agricultural facilities expanded food production within the immediate hinterlands of political capitals, making it possible to feed the urban populace. The desire for more land, greater crop security, and larger quantities of marketable food also led peasant households to invest in agricultural facilities on their own. State- sponsored agricultural investment can be distinguished from peasant investment through careful study: uniformity in the timing and techniques used in facility construction are the best indicators of state sponsorship.

The long-term environmental consequences of agricultural development was a potentially destabilizing factor in all ancient states. In Mesopotamia, irrigation led to the salinization of the soil, first causing agriculturalists to switch from wheat to more salt-tolerant barley and then to abandon salinized areas all together.

Tribute, Taxes, and Private Estates

All archaic states needed wealth to fund their centralized power. Taxes could be paid in labor, goods, or currency. A tribute in labor was least likely to provoke peasant resistance, since labor could be 'reciprocated' with food and drink, presented to workers by the state in a party-like atmosphere. This form of taxation may characterize the earliest states (i.e., states that still had to contend with kinship groups and kinship norms) or states that legitimated their rule with ideologies of collective wellbeing. A tribute in goods may have its origins in the spoils of war, tribute representing spoils paid on a sustained-yield basis. Agricultural staples and woven cloth were the most common forms of tribute goods, but metals, precious stones, and other exotic valuables were also collected. Tribute foodstuffs were used to feed state personnel. Tribute luxury goods enabled rulers to reward loyal servants and to control the formation of social identities.

Because of their bulk, tribute goods were often stored in provincial warehouses, potentially funding revolts by provincial leaders. Substituting a monetary tax for tribute goods reduced transport costs and provided more centralized control over wealth. But monetary taxation occurred only in conjunction with market systems, where money could be converted into needed goods and services.

Tribute demands often transformed rural landscapes and households. Greek farm families under Roman rule abandoned their rural farmsteads and moved to towns where economic diversification could supplement their incomes and provide the necessary cash for taxes. In the Valley of Oaxaca, the state's demand for maize led to the cultivation of more distant fields which, in turn, altered routines of food preparation. More dry foods (i.e., tortillas) were made so that meals could be carried and eaten away from home.

Peasant households sometimes tried to escape tribute payments. In Mexico under the Aztecs, maguey cultivation expanded, perhaps because its perishable sap was not easily appropriated by the state. In Mesopotamia, peasant families wishing to avoid taxation sometimes fled to the mountains, becoming nomadic pastoralists.

Urbanism

Archaic states provided the setting for the earliest cities i.e., large, socially-heterogeneous, permanent settlements. These cities were religious and political centers; their economic functions were much less important than is the case for modern cities. Cities housed the administrative machinery of the state, usually in a multi-roomed palace complex. Highranking nobles, bureaucrats, and military personnel resided in the capital so that their activities could be directed and monitored by the ruler. Most state capitals also contained shrines, temples, and the residences of high-ranking priests. The concentration of political elites in the capital provided a clientele for enterprising craftspeople, merchants, and other service providers, who swelled the urban populace. Early cities did not supply many of the tools or meager furnishings used by rural peasants; these were usually produced in hinterland towns and villages, by parttime craft specialists.

In several cases, the growth of ancient cities was accompanied by the emptying out of the countryside. Both Uruk (Mesopotamia) and Teotihuacan (Mexico) grew explosively at the expense of rural settlements. In these cities, peasant farmers and farm laborers made up as much as 75% of the urban population. Both push and pull factors may have moved farmers from the country to the city. The security, sanctity, and commercial opportunities of the city provided powerful draws; at the same time, rural people may have been forcibly removed to the cities in order to facilitate supervision by the state and to loosen their claims on the land.

Cities developed only minimally in early Egypt. In Egypt, the concentration of population along the banks of the Nile, and the ease of water-bourne communication up and down the

river, may have made it unnecessary to concentrate elites and rituals in urban centers.

Markets

Markets often appear in conjunction with cities. Anthropologists are divided on the issue of whether markets developed from the 'top down' or from the 'bottom up.' 'Top down' theorists postulate that markets developed from the demands of urban elites for food and status goods. 'Bottom up' theorists view markets as developing from the efforts of peasants to enhance the efficiency and/or economic security of their households by participating in specialized production and exchange.

Regardless of their origins, markets attracted the attention of political leaders. Market taxes were an important source of revenue to rulers, and markets provided an efficient means of provisioning cities. States provided both direct and indirect stimuli to market growth. Rulers promoted markets by offering merchants protection against thieves and bandits and maintaining market order. Indirectly, states stimulated market participation by peasant households. Tribute demands forced peasants to become more efficient producers, engaging in specialized production and market exchange. In addition, the social hierarchies that accompanied state formation sometimes prompted peasants to consume specialist-produced goods to enhance their social standing.

In the long run, markets weakened the state's control over the economy. Merchant guilds, formed during periods of state collapse, resisted state control of the economy. The wide array of goods offered for market sale made it difficult to enforce the state's sumptuary rules limiting certain forms of food and dress to state-designated groups. Buying and selling conferred economic power upon individuals who were not state functionaries.

Full-Time Craft Specialists

Many forms of craft specialization antedate the origins of states. In tribal societies, it is not unusual for households or entire villages to specialize in ceramic production, stone tool production, or even metallurgy. This craft activity is carried out on a part-time basis in conjunction with basic subsistence activities. Craft products are distributed in reciprocal exchanges to strengthen social ties and/or to acquire goods from other specialists. Rural, part-time specialization of this sort was also present in archaic states, often enhanced by the opportunities for exchange provided by urban markets.

In situations of incipient social inequality, some craft specialists produced very elaborate goods that required heavy expenditures of labor. These 'hypertrophic' goods (such as embroidered textiles, jade earspools, stone sculptures, heavy bronze vessels, and gold jewelry) were commissioned by aspiring leaders to legitimate their claims to social worth. The craftsmen filling these commissions were part-time specialists either living in their own households or as members of the leader's high-ranking family.

The earliest full-time craft specialists in archaic states were the dependents of state rulers. Rulers supported craft specialists to maintain exclusive control over their output. Controlling sumptuary goods enabled rulers to consolidate their power by rewarding loyal servants and controlling social identities. Thus, for example, the Inka ruler supported a certain number of yanakuna and aqllakuna, full-time specialists in metallurgy and elaborate textile production. Gold and silver jewelry and embroidered textiles were used by the ruler to denote statuses within the state hierarchy. Maya rulers sponsored elite kinsmen who specialized in the production of elaborate painted ceramic vessels. Used in royal funerary rituals, these vessels confirmed the noble status of families. Egypt's pharaohs supported entire towns of craftsmen dedicated to the preparation of royal tombs. Royal patronage accounts for the high levels of skill and artistry that characterize the finest works of archaic states.

Full-time craft specialization also emerged in more commercial contexts when a high demand for craft goods (usually for export trade) combined with developed transportation networks and a steady supply of marketed food. These conditions were met most fully in the Mediterranean world where the water-bourne transport of food staples from one broad region to another underwrote really large-scale production and exchange. In late precolonial India and China, reliable agricultural systems combined with riverine and oxcart transport yielded similarly high levels of commercial production and exchange.

Key Characteristics of Archaic States – Social Organization

Social heterogeneity is the defining characteristic of complex societies. In addition to the occupational diversity described above, the intersection of class, gender, and ethnicity created an array of social statuses and life histories in the ancient world.

Class Stratification

In the earliest states, the division between classes was based on political rather than economic status. A key division within society was between those who paid tribute and those who received it. Tribute was paid to the ruler who distributed it to servants of the state (usually close relatives). Key personnel were endowed with their own streams of tribute flow. Thus, the tribute-collecting class in archaic states comprised the ruler and his close relatives, high-ranking military personnel, government administrators, priests, and surviving elements of the pre-state nobility. For the governing class, wealth, power, and prestige coincided and were mutually reinforcing. Conversely, tribute-payers suffered a lower standard of living, a lack of formal power, and low social status.

Archaeological and historical research reveals significant variability within the commoner class. For example, Aztec households varied by size, composition, wealth, and ethnic affiliation. Rural households chose different combinations of agricultural production and craft activity. This variability complicates the traditional view that commoners were a homogeneous class. It suggests that commoners were divided by demographic, economic, and social factors.

Slaves constituted a class below commoners. Slaves were captured in warfare, purchased through the slave trade, or sentenced to servitude as punishment for crimes or failed debts.

Among Aztecs and Mayas, slaves were used as household servants, but they were never very numerous. In Mesopotamia, large numbers of female war captives worked at textile production, and this may have set a precedent for the use of slave labor in commodity production. The use of slave labor in commercial enterprises was extremely important in highly commercialized economies of ancient Greece and Rome.

Private property sometimes developed out of warfare-based economic systems. In China and Aztec Mexico, lands that were seized in warfare and redistributed to loyal soldiers constituted an early form of private property. In Mesopotamia, private property developed long after states arose, through the gradual sale of lands belonging to kinship units to secular or religious elites.

Gender

In *The Origin of the Family, Private Property, and the State* (1972 [1884]), Frederick Engels argued that the development of private property brought about the state (to maintain wealth differences) and the patriarchal family (to insure the legitimacy of inheriting offspring). In the process, women's status declined from a position of approximate equality with men to an inferior position. This was the 'world historic defeat of the female sex.' Modern historic and archaeological scholarship suggests that institutions such as private property and the patriarchal family are not universal characteristics of ancient states, nor is the subordination of women. Nevertheless, gender relations and ideologies were frequently renegotiated during the process of state formation, with results that were detrimental to women.

The status of women in states was undermined by several factors. First, states were commonly created and maintained through warfare, and war was usually men's work. Through warfare, men gained access to spoils, a form of wealth that was not household-dependent. In addition, rulers often glorified male warriors and rewarded them with administrative positions in order to maintain their loyalty. Thus, warfare provided avenues of wealth, prestige and power for men that were not available to women. Furthermore, rulers dismantled kinship groups, which were nodes of resistance to state rule. These kinship groups often provided the primary rationale and defense of women's rights in ancient societies, and when they were destroyed, women were left without social recourse. It is not surprising, therefore, that many archaic states favored men. Ancient Rome and ancient China both awarded great authority to male household heads. The Classic Maya and the Aztecs conferred public prestige upon male warriors, and men dominated these state governments.

However, the subordination of women to men was not universal. States that legitimated their rule with ideologies of collective wellbeing did not emphasize warfare and did not stress gender difference. These states might have included Teotihuacan (Mexico), the Harappan states of the Indus Valley, and Egypt under the pharaohs. In the Andes, a long tradition of parallel descent favored gender equality. Even in states where patriarchy was the norm, high-ranking women were wealthier and more powerful than lower class men (i.e., class trumped gender). In peasant families, women's contribution to the household economy often translated into approximate gender equality. In addition, women found forums for resistance outside of the state. Female oracles provided social critique in Oaxaca Mexico, ancient Greece, and the Andes.

Ethnicity

Ethnicity is an identity based upon a presumption of shared history and common cultural inheritance. Ethnic identity is shaped by both ethnic affiliation and ethnic attribution. Ethnic affiliation refers to individuals' own sense of group membership and the characteristics of the group as defined by its members. Ethnic attribution concerns the characteristics of the group as defined by outsiders.

States acted opportunistically and inconsistently in dealing with ethnicity. Sometimes they suppressed ethnic affiliation to weaken the resistance of subject groups to the state. At other times they encouraged ethnic affiliation to accentuate division within the commoner class. States also used derogatory ethnic stereotypes to legitimize their exploitation of subject peoples. For example, Aztecs depicted their Otomí subjects as lazy, improvident, untrained blockheads and gaudy dressers. Stereotyping and ethnic prejudice generally heightened ethnic consciousness and perpetuated ethnic heterogeneity within ancient states.

Key Characteristics of Archaic States – Religion and World Views

State Religion

All archaic states had an official religion with standardized temples and full-time priests. Rulers' patronage of religion may have sprung from either piety or cynical efforts to manipulate the subordinate class. Either way, religion provided a powerful political resource that was actively exploited by ancient rulers.

Many archaeologists argue that state religion was used to forge a unified polity out of distinctive subject peoples and to legitimize the ruler's authority. For example, Chinese rulers tried to force cultural uniformity upon all the groups that they conquered, and Confucian philosophers declared that just rulers held the 'Mandate of Heaven.' The Incas' effort to impose cultural uniformity on their subjects is archaeologically visible in provincial capitals where large plazas were constructed using Inca architectural forms. Local people gathered in these plazas to attend state-sponsored rituals.

In contrast, Aztec state religion was not geared to produce a uniform world view within the empire, nor to sanctify Aztec rulers in the eyes of their subjects. Rather, Aztec religion was intended to win the loyalty of a relatively small target group, the young men who formed the core of the Aztec army, by imbuing their military exploits with cosmological significance. In the Aztec hinterlands, distinctive forms of ceramic figurines suggest that commoners did not accept the state's ideology; on the contrary, commoners successfully maintained their own world view. Distinctive commoner ideologies may have been present in all archaic states, challenging the official point of view.

Monumental Architecture

The earliest monuments were megalithic tombs and earthworks built by groups that were still organized using kinship

principles. These monuments were probably constructed during communal rituals, when aspiring leaders sought social prominence by sponsoring group festivities. Under state rule, monumental construction increased in scale, creating some of the most striking icons of the ancient world: Egypt's pyramids, Mesopotamia's ziggurats, the colossus of Zeus at Rhodes. It is estimated that the great Pyramid of Khafu (Cheops) required 13 440 000 person-days of labor.

Some monuments may have been constructed by a willing populace, motivated by civic pride and religious devotion. This would have been most likely in states that legitimated their rule with ideologies of collective wellbeing. At Teotihuacan, for example, the Temple of the Sun and the Temple of the Moon may have been constructed in a surge of popular enthusiasm. In states relying upon coercive rule, monument construction expressed submission to the state. Aztec rulers invited subject communities to participate in the construction of the Great Temple in Tenochtitlan, and refusals to participate were considered acts of rebellion.

Through their size, monumental structures symbolized the ruler's exclusive link to supernatural forces. Monumental structures also expressed overwhelming power of the state and the fact of commoners' subordination. Large buildings and massive sculptures imposed themselves on social space and human psyches. In the words of Antonio Gilman (1996), they showed 'who was boss.'

Writing

Writing developed in archaic states for many different reasons. The earliest texts, from Mesopotamia at 3300 BCE, recorded the economic transactions of large temple estates. In ancient Egypt and Mesoamerica, writing was first used to record the exploits of rulers. The earliest Chinese inscriptions were questions carved on turtle carapaces and the shoulder blades of cattle for the purposes of divination. In all cases, writing was an elite activity. Writing can be regarded the product of elite efforts to establish and to preserve a single, authoritative record of events and to make its voice stronger than the spoken words of its subjects.

The Rise and Fall of Archaic States

In the 1970s, archaeologists believed that states arose to manage environmental problems. Since states are powerful administrative institutions, state officials can function as highly effective problem solvers. They can construct large-scale irrigation networks, insure populations against crop failure, administer markets, organize warfare, and sponsor long-distance trade. Archaeological evidence confirms that archaic states did oversee some of these activities. However, the evidence for these activities usually dates to a few centuries after state formation; thus, the problem-solving capacity of states does not appear to account for their origins.

More recently, archaeologists have begun to account for state origins by examining how individuals acquire social power. In one model, dynamic, ambitious leaders assemble coalitions of followers by sponsoring feasts and distributing gifts. Each leader with his followers then competes against other leaders and followers to establish dominance, first on the local, then on the regional, level. In these systems, personal prestige is emphasized, and dominance may be maintained through naked force. In a second model, leaders attract a broader following, by appealing to ideologies of collective wellbeing. State formation is more 'volunteeristic,' resembling a religious movement, and there is broad-based participation in collective rituals and public monument-building. Leaders are more anonymous, and when force is used, it is used on behalf of society as a whole. It has been suggested that the flamboyant Maya and the Shang rulers might exemplify the outcome of the first (individualizing) strategy, whereas the Teotihuacan (Mexico) and Harappan states might be products of the second (corporate) strategy.

Archaic states were complex, often fragile, social structures. Social dominance required balancing the needs and power of diverse social segments. Sudden shocks and long-term problems threatened the delicate balance. Over-population, excessive tax burdens, climatic deterioration or invading barbarians, all threatened to topple archaic states at one time or another. Egypt's Old Kingdom collapsed when provincial officials became increasingly independent of the pharaoh's rule; the Middle Kingdom fell because bureaucrats at the center absorbed too much of the state's wealth. Competition among the independent Classic Maya kingdoms led the Maya to overexploit their resources and, finally, to abandon their homes. The surprise is not that archaic states eventually collapsed, but that ruling elites could devise institutional structures that enabled states to endure, sometimes for centuries at a time.

Abstract

This article outlines the main features of present-day statistical software by reviewing its development from the (late) 1950s to the present time. It puts a focus on the management and analysis of social science data. The article concludes with a discussion of present-day software alternatives for social scientists.

Introduction

Since World War II, social sciences have become increasingly empirical. This does not mean that before World War II social sciences were only doing theories without any links to real world problems or that there were no empirical investigations of real world phenomena. But it is certainly true that empirical studies analyzing quantitative data were clearly outnumbered; and the few that existed were using a methodology that was much less statistically sophisticated than the quantitative analyses that are published nowadays in top social sciences journals. The main reason for this development is obvious: It is the availability of user-friendly software that allows *social scientists* to read, manipulate, and analyze complex data with a few keystrokes or some simple commands, even if they are no specialists in statistics or information science. And it is also true "that the most important changes in *statistics* in the last 50 years are driven by technology. More specifically, by the development and universal availability of fast computers and of devices to collect and store ever-increasing amounts of data" (De Leeuw, 2011; emphasis added).

Quantitative data can be analyzed with all kinds of tools: with paper and pencil, pocket calculators, office software, and specialized statistical software. This article focuses on *statistical software* and not on software that can also be used for statistics (*software for statistics*; e.g., a spreadsheet program). It does so by putting a special emphasis on social science data. While a statistical program simply needs a rectangular matrix of numbers to do its calculations, social science data have a least two characteristics that need special attention. First, the numbers are often not the result of quantitative measurement, they rather indicate ('code') certain characteristics of the unit of analysis (e.g., being a male or female respondent). Second, sometimes, for certain units, no number is available, either because the corresponding variable does not apply to that unit (e.g., the type of job for a respondent that is unemployed) or because the corresponding information is not available (e.g., when an employed respondent refused to provide information about his job). As a consequence, statistical software specifically designed for social science data must provide possibilities to complement the data matrix with additional information about the codes (labels) and missing data. Moreover, statistical computations have to control for the missing information. Finally, but this applies to all kinds of quantitative data, data sets often require a great deal of manipulation before they are ready for analysis. Therefore, any statistical software has to include some functionality for data manipulation, sometimes nearly as complex as a data bank software that allows to index, select, append, and merge all kinds of data sets. One should also note that nowadays statistical software is not confined to the analysis of numbers. The data may also include text and thus statistical software also provides (often limited) possibilities for text analysis.

Due to the rapidly changing software market, it is not possible (and not useful) to give a complete overview of all available statistical software. Instead, this article outlines the main features of present-day statistical software by reviewing its development from the (late) 1950s to the present time (Section A Brief History of Statistical Analysis Packages). The article concludes with a discussion of our present-day alternatives (Section What Choices Do We Have Today?).

A Brief History of Statistical Analysis Packages

The following historical sketch describes the development of statistical analysis packages in three steps that roughly summarize the innovations of the 1960s/1970s, the 1980s, and the 1990s. To understand the historical legacy of the first packages (and the innovations of their followers), we start with a résumé of the tools that were available to social scientists before the advent of statistical analysis packages.

The following historical sketch is closely linked to the development of information technology. From the very beginning, statistical applications were determined by the amount of computation necessary to draw conclusions from the data. In the early times of modern statistics computing time was clearly a restriction. Salsburg (2002) estimated that Sir Ronald Fisher's computations for one table in his 'Studies in Crop Variation. I' took about 185 h on his mechanical desktop calculator. Nowadays, with first the electronic (mainframe) computer and then the personal (micro) computer, computing time is increasingly less of an obstacle. Moreover, the development of programing tools and interfaces made this hardware more and more user-friendly. In addition, the refinement of graphical interfaces has revolutionized the display and exploration of data.

The Time 'Before' Statistical Analysis Packages

Before the advent of statistical software on electronic computers social scientists had to live with mechanical computers and tabulating machines. Larger data sets that could not be

 http://dx.doi.org/10.1016/B978-0-08-097086-8.03023-3

handled manually had to be transferred on cards using specialized coding systems that represented the information in digital form by the presence or absence of holes in predefined positions. These punch cards are also called Hollerith or IBM cards, because Herman Hollerith invented both the storage medium and the processing technology (tabulating machines) to analyze the stored information. He founded the Tabulating Machine Company, which was one of four companies that merged to form Computing Tabulating Recording Company, later renamed IBM. The Eleventh United States census in 1890 was the first census to use this technology. From then on, until the 1950s, this technology was used in all industrialized countries to process business, government, and scientific data. In the 1950s, magnetic tapes and new electronic input devices were introduced to store mass data. However, not till the 1960s, the punch card technology was gradually replaced by magnetic tapes as more capable electronic computers became available.

The early times of (quantitative) social research were dominated by punch cards and tabulating machines. Since the punch card provided only 80 columns to store information, all kinds of coding systems were invented to store as much as possible information on one card. If one card did not suffice for the data of one unit of analysis, one had to use several cards for each unit, but then also to make sure that the whole card deck with all the information for the entire sample remained in correct order. Biographies and obituaries of older social scientists are full of anecdotes about how they fought with tabulating machines, multiple punch systems, and disordered card decks that fell down on the floor. It was not before the advent of the transistor based (so-called second generation) electronic computer in the 1960s (e.g., the IBM 7090), that some larger pieces of software developed that allowed nonspecialists to manage and analyze social science data.

One was the DATATEXT package (Armor and Couch, 1972) developed at the end of the 1960s in Harvard, the other was a package of statistical routines for biomedical research (BMD), which was developed at the end of the 1950s at the University of California in Los Angeles (Dixon and University of California, 1967). (For better readability, in this article all package names are written in capital letters.) Both were still carrying the footprints of the punch card times. DATATEXT provided, besides statistics, all kinds of routines to cope with 'messy' card decks and multiple punch systems. BMD was simply a collection of programs; each one for a specific statistical method (e.g., analysis of variance), but all using the same command language and input–output system that expected the data to be prepared in advance in a rectangular data matrix. Program commands had to be written on punch cards using certain columns for command names and other columns for the command parameters. While DATATEXT used command keywords, BMD was controlled entirely by numbers.

The exclusive mode of processing and analyzing data was the so-called batch mode. Program commands were written on punched cards and, together with a card deck of data, were input into the computer. Depending on the power of the computer and the number of other active batch jobs on the computer, it took some time (sometimes even days) until the user would see an output of the program results. Very often, the output only showed an error message, because the user misspelled a command or did not follow the fixed input scheme for the commands. Then the whole process had to be repeated again, often several times until all errors were eliminated. At these times, the statistical analyses were simple (compared to nowadays level of sophistication), but the process was very time consuming and not all social scientists (especially outside the US) had access to electronic computers. Not surprisingly, only a small and selective group of social scientists used this technology.

The Time of the Mainframes

The explosion in the use of computers began with the third generation of electronic computers using integrated circuits or microchips. The IBM System 360, first shipped in 1965, is an example of such a third generation computer. These were still large (mainframe) computers, both in terms of size and prize. Hence, only larger organizations could afford them. In most cases, they were part of a computing center that offered computer time as well as input and output devices to a larger group of users. Input devices could still be card readers, but increasingly became computer terminals equipped with a keyboard and a screen. In principle, this allowed some kind of interaction between the user and the computer or its software. Several users could work concurrently with the computer, as operating systems included routines to share computing resources between users (so-called time-sharing systems).

This new generation of electronic computers was very consequential for all statistical analysis packages that existed so far. Designed for second generation computers and their operating systems, they were simply incompatible and could not be used anymore. As a collection of single statistical programs, BMD easily made the transition and, equipped with a new name: BMDP, used keywords (and not numbers) for the commands (University of California and Dixon, 1975). However, BMDP's target group were health scientists. Social scientists missed an alternative to DATATEXT, whose transition to the new generation of electronic computers came too late.

At that point, a new software, the Statistical Package for the Social Sciences (SPSS), had already started its success (Nie et al., 1970). It was developed around 1968 by social scientists at the University of Chicago and its fast diffusion in the market showed that its designers had built a product that satisfied the needs of its target group, the social scientists. One of the reasons for its success story was the program manual, which – besides describing the commands – provided applied introductions into all statistical techniques; and these introductions were easy to read even for those without a comprehensive statistical education (however, at the cost of not documenting the algorithms used for the statistical techniques). Wellman (1998) considered it one of sociology's most influential books because it allowed ordinary researchers 'to do their own statistical analyses'. Another reason for the success of SPSS was its availability on different computers and operating systems. In the 1970s, SPSS dominated as *the* tool for social science data analysis, while BMDP remained a specialist tool for the statisticians.

Although written for a new generation of computers, both packages still had features that reminded of the punch card era. A prominent example is that SPSS expected parameters for its

commands to start exactly in the 16th column of the command line. Although, as mentioned, user–machine interaction was possible, BMDP and SPSS expected a batch of commands (a 'program'), which then would be executed without intervention by the user. The way designers of statistical analysis packages thought about their users at that time was still not much different from the former 'batch mode' times. When intervention was not possible, and when program output was mostly provided by line printers, possibly in a distant computing center with quite some turnaround time, users chose the 'safe' way of producing results. They rather asked for everything ("…ALL BY ALL, STATISTICS ALL"), instead of asking for the results that were important. Moreover, most of the data management functions of DATATEXT were lost. BMDP as well as SPSS expected a rectangular matrix and the user had to use the supplied data generation commands for data management and cleaning.

All in all, statistical analysis packages introduced with the third generation of electronic computers were characterized, on the one hand, by providing easy access to the statistical tools of data analysis, but also, on the other hand, by the absence of any tools for data management. Moreover, they did not use the potential for user intervention and processed the commands in batch mode. Finally, a more technical point: The typical storage medium of that time was the magnetic tape, which could only be read and written sequentially. Random access memory was scarce and mostly processed sequentially (as if it would be a magnetic tape). Certainly, sequential storage media are a severe restriction for complex data bank systems. Nevertheless, the data management gap was filled in the second half of the 1970s by two software products: SIR/DBMS and SAS.

The mnemonic SIR stands for a data bank management system (Robinson et al., 1980) that was quite popular in the social sciences because it provided, on the one side, simple commands to manage a relational data bank and, on the other hand, the ability to output the contents of this data bank to any kind of statistical analysis package. For example, the German Socio-Economic Panel Study, a renowned panel study of the German resident population was managed for quite a while with SIR/DBMS. However, as more and more statistical analysis packages included the most important data management procedures into their functionality, SIR/DBMS more or less became a niche product.

SAS was developed almost as the same time as SPSS by computational statisticians at North Carolina State University (SAS Institute, 2013). While at the beginning a statistical software for large agricultural data sets, it developed into a comprehensive statistical package with often more functionality than its competitors and with a strong emphasis on handling large and complex data. For a long time, it was available only on IBM mainframes, which clearly restricted its diffusion. Later on, when it was available on all kinds of machines it became quite popular and a serious competitor for SPSS. In 1976, the inventors of SAS formed the SAS Institute Inc. and increasingly marketed SAS as a high-end software product mostly targeted at researchers in private business. The accompanying price policy made SAS difficult to afford for researchers in publicly funded academic organizations and hence restricted its popularity in this part of the market for statistical software.

All in all, the most important statistical software packages during the era of the mainframes were (in alphabetical order) BMDP, SAS, and SPSS. According to De Leeuw, "the three competitors differed mainly in the type of clients they were targeting. And of course health scientists, social scientists, and business clients all needed the standard repertoire of statistical techniques, but in addition some more specialized methods important in their field. Thus the packages diverged somewhat, although their basic components were very much the same" (De Leeuw, 2011). This does not mean that no other statistical analysis packages were available. On the contrary, important centers of statistics or survey research and individual researchers developed similar systems: for example, to name just a few, MINITAB from Penn State, OSIRIS from the Institute for Social Research at the University of Michigan, P-STAT from Princeton, GENSTAT from Rothamsted Experimental Station, or ALMO developed by Kurt Holm.

Some of these 'other' packages also introduced important innovations to the design of statistical software. GLIM, for example, was notable for encouraging an interactive, iterative approach to statistical modeling, besides providing a unified framework for fitting a wide range of generalized linear models (the GLIM syntax could be summarized on two (!) sheets of paper). It also allowed users to define their own macros and hence, provided an open programing environment compared to the 'closed shops' of SPSS and its competitors. SYSTAT, to name another example, was a statistical analysis package that put a special emphasis on statistical graphics.

The Advent of the Microcomputer

Indeed, by the end of the mainframe era, the terrain was prepared for social scientists to do statistical analyses 'themselves'. The software was there, its use was increasingly included in university teaching, and even the computers came a bit closer to the users with so-called mini computers such as Digital Equipment's Vax or Hewlett–Packard's HP3000 that provided computer resources to smaller workgroups. Yet, it was IBM's personal (micro) computer that really 'democratized' the use of statistical analysis packages. Indeed, with a PC on one's desk, everybody could manage and analyze large amounts of data. Besides bringing (rapidly increasing) storage and computing resources to the individual researcher, the main innovation of this fourth generation of computers was its user interface. From the very beginning, the user had total control on what was going on in his computer. But quite soon, operating systems for microcomputers provided graphical user interfaces (GUIs) with windows, icons, menus, and pointers that made user–machine interaction much easier.

All major statistical analysis packages made the transition to this new world of personal computing. Commands could be written and executed in a command window or chosen from a menu, and the results were shown in a separate output window that could be copied and pasted into other software (e.g., in word processors for report writing). From now on, statistical analysis packages could be used interactively. Commands and their results could be easily tested and revised, if the results did not match the research interests of the user. Commands need not to be remembered or taken from an accompanying printed manual, because the packages included

help menus, and manuals were stored electronically with the program. Nevertheless, for replicating the analysis and for computer-intensive tasks, the final commands had to be stored in a syntax file that could be executed again in a batch-mode-like fashion; a small reminiscence of the 'good old times', but useful and necessary. What also remained from the mainframe time was the massive output. Statistical analysis packages transferred from the mainframe era were still showing all numbers that ever could be of interest. Obviously, the interjection of GLIM was not heard to show only those numbers that the user needs for making the next decision.

During the microcomputer era we also observed a second generation of statistical software that made use of the new technologies and did not have the baggage of the mainframe era. Some of them made heavy use of the new graphical capabilities and emphasized visualization and exploratory data analysis. JMP, a computer program developed in the 1980s by the JMP business unit of SAS Institute, was such an example. It was created to take advantage of the GUI introduced by Apple's Macintosh, but nowadays is available also for other operating systems. The most prominent feature of JMP is its ability to really look at multivariate data and to screen the data from different perspectives.

STATA is another example of second generation statistical software. It was created in 1985 by the UCLA graduate William Gould together with his colleagues at Computing Resource Center, a private company, which in 1993 moved to Texas and now is named StataCorp LP (Cox, 2005). STATA is also a general-purpose statistical analysis package and at first sight, looks very similar to its relatives from the first generation (BMDP, SAS, and SPSS). It also had a command line interface, and did not get a GUI until 2003. However, from the start, it emphasized computation speed, extensibility, and user-contributed code. Computation speed is of utmost importance, if one wants to support the interactive use of the program. To this end, STATA is reading and writing all the data into the (fast) computer memory, while its relatives read and write the data (often sequentially) from slower memory devices. Within STATA one can also write macros and programs and in doing so, extend the program functionality to one's own needs. Users can publish their programs on the Internet or on Statacorp's servers. STATA itself makes heavy use of the Internet, both to update the program, but also to download data and user code. More than its relatives (perhaps with the exception of SAS) it tries to tie in its users. One could even speak of the 'STATA community'. It organizes user conferences, has a book series and a peer-reviewed journal, provides an e-mail Listserver for user discussions, and the very informative program documentation, both in terms of applications and technicalities, is available with the program and online. Nowadays, STATA is very popular in economics, sociology, and political science, with a strong focus in academia. It is especially attractive for its computing speed, extendibility, and prize.

From Statistical Program Packages to Statistical Analysis Languages

In the early 1990s, another type rather than a new generation of statistical software came into play. These were not preprogrammed analysis packages, but rather programing languages with a strong focus on statistical analysis. All of them have the S language as common ancestor, which – starting from 1975 – grew out of Bell laboratories; hence, a rather old development and not a new generation (Chambers, 2008: pp. 475–478). According to De Leeuw, a statistician, "the statistical techniques […] were considerably more up-to-date than techniques typically found in SPSS or SAS" (De Leeuw, 2011: p. 5). But it remained a tool for the specialists, although it was freely available for some time to academic institutions. Also its commercial version S-PLUS hardly diffused into the wider circle of applied researchers.

The followers of S in the 1990s were LISP-STAT and R. Both languages are open source products and available on the personal computer, which explains – at least in the case of R – their popularity in and outside the community of statisticians. LISP-STAT was developed by Tierney (2009) and provided statistical tools embedded in a Lisp interpreter (Lisp is a programing language that is often used in artificial intelligence research). Using a (general) programing language as the environment provides lots of opportunities for extending LISP-STAT. According to the Web site, it puts "an emphasis on providing a framework for exploring the use of dynamic graphical methods". But LISP-STAT's development ceased by the end of the twentieth century.

R was written as an alternative implementation of the S language (Ihaka and Gentleman, 1996). Due to its extendibility by user-written programs and easy availability as an open source product, its dispersion in the market has increased dramatically in recent years. De Leeuw says: "R is many things to many people: a rapid prototyping environment for statistical techniques, a vehicle for computational statistics, an environment for routine statistical analysis, and a basis for teaching statistics at all levels. Or, going back to the origins of S, a convenient interpreter to wrap existing compiled code" (De Leeuw, 2011: p. 6). But the extendibility is also a problem. For example, it is quite possible that several user programs exist, which address the same problem. Which one to choose? Sometimes the documentation for this user-written code is insufficient and who tests whether the programing is reliable and efficient? If social scientists want to have the same basic functionality as their old statistical analysis packages, i.e., labeling variables and values, coding missing data, etc., they have to download several user-written programs to their base R installation. Which the most useful ones are, can certainly be found somewhere in the Internet. But how does the applied social researcher find this information, if it is not in textbooks on R, which by the way are mostly written by statisticians and for their audience.

What Choices Do We Have Today?

Without the innovations of information technology, the analysis of social science data would not have come so far. With the help of the computer, we collect and store data in virtually unlimited amounts; and it provides us with the computation power to do all kinds of sophisticated statistical analyses. For example, maximum likelihood as a method of estimation has been known for centuries, but it needed the electronic computer to apply it to real-world data. Moreover, classical parametric

procedures have been supplemented with computer-intensive, nonparametric methods such as resampling to compute standard errors and confidence intervals. Bayesian statistics have become popular in recent years due to the availability of Markov chain Monte Carlo methods, which allow sampling from probability distributions, which is critical in Bayesian Statistics. Finally, the availability of computing power and GUIs has made the dream of really looking at data come true.

Besides the development of the hardware, the Internet of computers worldwide has revolutionized the acquisition, storage, and access to social science data. Whereas the classical statistical problem was to make the most out of limited data, today the challenge is to process large data samples. Only with the power of present-day computers, social scientists have all the means to analyze these vast amounts of information.

With respect to software, our historical account has shown the alternatives that are available to social scientists today. Basically, there are three: (1) general-purpose programs like SPSS, SAS, or STATA (BMDP has become a niche product), (2) statistical analysis languages, most prominently R, or (3) other software that can also be used for statistics. As Brian Ripley, Professor of Applied Statistics at the University of Oxford, once said at a conference of the Royal Statistical Society: "Let's not kid ourselves: the most widely used piece of software for statistics is Excel" (Ripley, 2002). Naturally, statistical add-ons exist also for this third alternative (e.g., ANALYZE-IT, NUMXL, or SIGMAXL). Besides these main alternatives, there are lots of other programs often designed for specific purposes; e.g., MPLUS for structural equation modeling, HLM for multilevel regression, and many others. Wikipedia is an excellent information source for all kinds of software and provides an up-to-date list and comparison of statistical packages. The Journal of Statistical Software, according to its Web site, publishes "articles, book reviews, code snippets, and software reviews on the subject of statistical software and algorithms." Software reviews can also be found in major statistical journals.

This bulk of software and alternatives has pros and cons. One of the advantages is that users can compare. This does not only mean looking for the best alternative, it also implies that users can test the reliability of the available software. In most cases, social scientists will not have the expertise to check the accuracy of the underlying algorithms, but if alternative software does not reproduce the results of their favorite software, then possibly something is wrong and they should consult an expert. For example, regular tests of statistical software show that numerical accuracy cannot be taken for granted (see, e.g., Keeling and Pavur, 2007). One of the disadvantages is, of course, that the uninformed user is easily lost. This is especially true for open source products, as the example of R shows (see the discussion above). This does not mean that proprietary products are without problems, but with such a contested market for statistical software every commercial provider of statistical software has a high interest in providing a reliable product (naturally, the incentive is lower for providers of software that is not designed for statistics in the first place).

Our historical review has shown the rise and fall of various software products. As a final point, this raises the question of what makes a product successful in an obviously very dynamic market with significant competitors, some of them even providing their products for free. One precondition is, of course, being at the forefront of data management and data analysis. A second condition is user friendliness, which does not necessarily mean simplicity. Users accept that data analysis may be a complicated matter and therefore, will accept some complexity, but the easier this complexity is to understand through the handling of the program, the more user-friendly the software is. Third, having a clear and solvent target group seems to be a precondition for commercial success. SAS, focusing primarily on private business, is a typical example of this strategy (SPSS, now owned by IBM, seems to go in the same direction of focusing on users in private business). Academia, on the other hand, is an unreliable and unfaithful clientele. First, they know everything better and try to do it themselves. Second, academia, compared to private business, is rather poor. Hence, if a software provider is not able to tie in its users or has something to sell that others do not supply, it is quite probable that the software will not survive.

Abstract

In hierarchical data structures, observational units at one level are nested within units at other levels. For longitudinal data on individuals, within-person observations are nested within individuals. Within-person (micro) observations are generally more like each other than observations sampled randomly across individuals (contexts). In generalized regression models, several approaches can accommodate this lack of independence: (a) random effects, (b) fixed effects, (c) marginal models in the non-Gaussian case, and (d) regression coefficient covariance matrix adjustment. Each approach has specific advantages and drawbacks. Fixed effects are often used in situations in which a key assumption of the random effects approach is thought to be implausible. In those instances, the use of marginal models or regression coefficient covariance matrix adjustment would also merit reconsideration. Where more than one approach can justifiably be applied – and there are many such cases – estimation results can be method-dependent, leading to different conclusions about the effects of specific covariates. In addition, particularly for the random effects approach, alternative methods of estimation can yield somewhat different results, as can different algorithmic implementations of the same method across software packages. The impact of small within-context sample sizes in unbalanced designs merits further exploration. Where possible, researchers should consider whether their conclusions are method- or algorithm-dependent.

Multilevel, or hierarchical, data are blocked or clustered. Children within families; individuals within organizational units; longitudinal data on individuals; repeated measures on individuals; organizational units within larger organizations; multistage sample surveys; and time series of cross-sections exemplify multilevel or hierarchical data structures. When data are clustered, each observation counts for less than it would if the data points were independent. If clustering is ignored, statistical inference can be faulty. With clustering, regression methods that assume independent observations provide inefficient and possibly biased coefficient estimates, and associated confidence intervals that are too narrow. In the context of regression modeling, any method that attempts to take account of clustering is multilevel.

Several generalized regression methods are commonly used in the analysis of hierarchical data. Hierarchical or random coefficient models are multilevel. So too are fixed effects models, marginal models, classical single-level estimation followed by regression coefficient covariance matrix adjustment, and hybrid approaches. The choice of an approach for a particular research problem must depend on the goals of the research and assessment of the design and measurement deficiencies presented by a particular body of data, and is often consequential. Multilevel modeling approaches emphasize different aspects of the data, vary in the nature and stringency of their assumptions, and support different kinds of descriptions and interpretations. Poor choice of method can lead to the application of an incorrectly specified model, and thereby to good estimates of the wrong quantities.

Random Coefficient Models

The random coefficient model offers a compelling formulation that is consistent with the social scientific goal of understanding how units at one level affect, and are affected by, units at other levels. Consider a design with two levels, and suppose that there is a single level-1 regressor (X), a single level-2 regressor (G) that is by definition *constant* over all level-1 observations within a context, and that the dependent variable (Y) is Gaussian distributed conditional on X and G. The random coefficient model can be expressed as

$$Y_{ij} = \beta_{0j} + \beta_{1j}X_{ij} + \varepsilon_{ij} \qquad [1]$$

with

$$\begin{aligned} \beta_{0j} &= \eta_{00} + \eta_{01}G_j + \alpha_{0j} \\ \beta_{1j} &= \eta_{10} + \eta_{11}G_j + \alpha_{1j} \end{aligned} \qquad [2]$$

where $j = 1,2,\ldots,J$ denotes contexts (level-2 units), and $i = 1,2,\ldots,n_j$ denotes individuals within contexts (level-1 units). The level-2 equations (eqn [2]) assert that the level-1 intercepts and slopes vary over contexts as linear functions of G. There is often justification for supposing that the within-context coefficients depend on contextual characteristics. It is appealing that the dependence includes random error components (α_{0j} and α_{1j}).

Assumptions about the error structure of this two-level model are that, for each context, the level-1 errors follow the Gaussian distribution, are centered on zero, have constant variance, and are independent. The error variances may vary over contexts. The level-2 errors are also Gaussian distributed, centered on zero, independent within equations, and have constant variances. The level-2 errors may be correlated across equations. It is further assumed that the level-1 errors are orthogonal to the level-2 errors, and that all error terms are orthogonal to X and G. The orthogonality assumptions are needed to secure consistent estimates of the ηs.

Many generalizations of this model are possible – coefficients can be constrained to be nonrandom; the

dependent variable may be discrete, counted, truncated, ordinal, or time to event; there may be more regressors at any level as well as more than two levels; the nesting of levels may be cross-classified; different assumptions about the functional forms of the distributions of the errors can be made; and the assumption of independence of errors within level-2 (or higher) units can be relaxed. Nevertheless, the assumptions of orthogonality between regressors and errors, and of cross-level orthogonality between error components, continue to remain important. Until that is no longer so, the credibility of an application of a random coefficient model rests on the plausibility of these assumptions, which should be thought of as inextricably linked to the systematic components of the model, and not as the fine print of a contract that is never read, much less enforced.

However compelling it may be on substantive grounds to specify the random coefficient multilevel model as eqns [1] and [2], substitution of eqn [2] into eqn [1] results in the equivalent mixed model representation,

$$Y_{ij} = \eta_{00} + \eta_{01}G_j + \eta_{10}X_{ij} + \eta_{11}X_{ij}G_j + \left(\alpha_{0j} + \alpha_{1j}X_{ij} + \varepsilon_{ij}\right) \quad [3]$$

which demonstrates that treating intercepts and slopes as dependent on G is the same as supposing that Y depends on X, G, and their cross-level (product) interaction.

Random coefficient models with Gaussian errors are commonly estimated by maximum likelihood or restricted maximum likelihood. For binary response the prevalent methods are marginal and penalized quasi-likelihood, although Bayesian methods based on Markov Chain Monte Carlo estimation are also beginning to be used. A consensus on preferred methods of estimation of multilevel binary response and other nonlinear (non-Gaussian) models has yet to emerge. Estimation of multilevel models is iterative and computationally intensive, more so for non-Gaussian cases. Especially for these cases, researchers are well advised to check numerical estimates across algorithms, methods, and software. Other problems, such as substantial design imbalance in combination with context size, also need to be evaluated for their potential impact on numerical estimates (*see* Estimation: Point and Interval; Guilt; Markov Chain Monte Carlo Methods).

Fixed Effects Models

The fixed effects model does not require the assumption of orthogonality between X and α_0 inherent to the random coefficient model. It can be written as

$$Y_{ij} = \beta_0 + \beta_1 X_{ij} + \beta_2 X_{ij}G_j + \delta_j + u_{ij} \quad [4]$$

where the δ_j are between-context contrasts, and the u_{tj} are assumed to be classical Gaussian errors. Relative to the random coefficient model, the additive term in G has been dropped, and the intercept and slope are no longer allowed to vary randomly over contexts, although each context is allowed its own intercept and the cross-level interaction is retained. The δ_j absorb the additive component of *all possible* G-variables, not just the finite number that can be included in eqn [3]. Additive components for any level-1 regressors that do not vary within contexts are also absorbed by the δ_j.

In the fixed effects approach, 'fixing' the between-context contrasts means that the contexts are themselves assumed to be fixed, in the sense that statistical inference is conditional on the particular selection of contexts present in the data. Because the contrasts can be defined as the coefficients of a set of indicator variables that assign individuals to contexts, there is no need to assume that context membership is orthogonal to X. This is a critical difference between the fixed effect and random coefficient models. If the assumption of orthogonality between X and α_0 is implausible in the random coefficient model, and it can be when the list of G-variables is incomplete, then the fixed effects model provides an alternative that solves the problem. In the Gaussian case, the fixed effects model is a conventional regression model. When J is large – and often when it is not – there may be little interest in describing estimated values of the δ_j, in which case estimation of the other covariate coefficients can be performed after within-context centering of the variables. For a binary response variable, conditional logistic regression can be used to estimate fixed effect models (Chamberlain, 1980). In this case, the context contrasts are not estimated, although additive context differences are controlled. Software for fixed effects estimation is widely available.

If it is desired to obtain estimates of the additive component of the contextual variables, then the fixed effects approach is not the method of choice. Also, in the binary response case, conditional logistic regression does not necessarily use all of the data, and in this sense may be inefficient (*see* Linear Hypothesis; Multivariate Analysis: Discrete Variables (Loglinear Models)).

Coefficient Variance Estimates Adjusted for Clustering

The adjusted coefficient variance estimator in common use for multilevel analysis is a robust estimator. In actual applications, care must be taken to ensure that the robust estimator selected includes an extension of the algorithm for the general robust estimator that accommodates clustering. With the robust estimator, it is possible to specify a model whose systematic component is identical to that of eqn [3], and whose error component need not be independently and identically distributed, Gaussian distributed, or orthogonal to the regressors. The robust equivalent of eqn [3] can be expressed as:

$$Y_{ij} = b_0 + b_1 G_j + b_2 X_{ij} + b_3 X_{ij}G_j + e_{ij} \quad [5]$$

Least squares computation can be used to produce coefficients whose estimated variances and covariances are subsequently adjusted for context membership. The coefficients will be unbiased estimates of the corresponding terms in eqn [3], if the orthogonality assumption is satisfied. The standard errors will be adjusted for clustering and other sources of heteroscedasticity regardless of whether this is so. When eqn [3] is true, confidence intervals for its coefficients obtained by prevailing methods will tend to be smaller than confidence

intervals based on the robust clustering adjustment associated with eqn [5].

The robust approach is also an alternative to the fixed effects approach. The latter achieves orthogonality between the regressors and the error component by including context membership in the systematic component of the model, but is unable to include main effects of contextual variables even though it controls for all possible contextual variables. In the robust approach coefficients of contextual regressors are estimated, but all possible contextual variables are not controlled. Coefficient standard errors are adjusted for clustering, but the coefficient estimates are not efficient.

The robust, variance adjustment approach to multilevel analysis has been extended to models of discrete and counted outcomes, and to survival problems, and can be used where a fixed effects approach is not available. Nevertheless, where it can be justified, explicit incorporation of clustering into model specification is preferable to *post hoc* adjustments of estimators that ignore clustering (*see* Sample Surveys: Model-Based Approaches).

Marginal Models

When Y is a discrete or count response variable, it is possible to specify a multilevel model in which the within-context correlatedness of observations is incorporated as a side condition on the model, rather than as a consequence of a random intercept. For Y binary and ω_{ij}, the logit of 'success' for the ijth observation, the multilevel dependence of Y on regressors, can be written as

$$\omega_{ij} = \beta_0 + \beta_1 G_j + \beta_2 X_{ij} + \beta_3 X_{ij} G_j \qquad [6]$$

with an additional specification indicating the pattern of correlation between observations within a context (corr(Y_{ij}, $Y_{i'j}$), $i \neq i'$). Specifying that all pairs of observations within a context are equally correlated corresponds to the assumption of correlatedness induced by a random coefficient model, but virtually any pattern can be specified.

Models that characterize the marginal distribution of Y as a function of regressors are said to be marginal models. The model of eqn [6] and its side condition on correlated observations is a member of this class. The generalized linear model (McCullagh and Nelder, 1989), a unifying theoretical framework for the linear model and discrete and count response variables, has been extended to allow for the analysis of multilevel data (Liang and Zeger, 1986; Zeger and Liang, 1986). This extension, known as the generalized estimating equations approach (GEE), provides a marginal model (population average) alternative to random coefficient models when Y is discrete or a count. Equation [6] can be estimated using the GEE method.

Gaussian random effects models sustain a marginal model interpretation of regression coefficients. Random effects models for discrete and count response variables do not. Marginal models are appropriate when the analytic goal is to infer how Y depends on covariates for a population of level-1 units averaged over contexts. Random effects models are appropriate when within-context estimates are desired. For the logistic response case, the estimated coefficients of marginal models tend to be smaller in absolute value than the corresponding coefficients in random effects models (Diggle et al., 1994: 141).

Marginal models for Y discrete or a count can be estimated for a broad range of structures of potential within-context correlation; random coefficient models for discrete and count response variables currently cannot. Computation is fast (iterative generalized least squares), and estimation is relatively straightforward compared to binary response random coefficient models, although issues surrounding optimal characterization of within-context correlation and estimation of coefficient standard errors continue to attract attention.

Omitted Variables

Omitted variables in random coefficient models are of particular concern when they are endogenous, that is, correlated with Y and the included regressors, because they induce coefficient bias. The fixed effect approach provides one solution to this problem when the omitted variables are contextual. There are others: measurement of omitted variables, random assignment to contexts, and instrumental variables estimation.

Measuring the omitted variables is not an option in secondary analysis or in the midst of primary analysis – by then the data have been collected and returning to the field is generally infeasible. This should not, however, preclude future attempts to extend the range of measurement.

Random assignment to contexts presumes that an experimental design is feasible in the study of a particular phenomenon. Often it is not. Even when randomization is possible, it is not necessarily well suited to answering certain kinds of questions (*see* Experimental Design: Randomization and Social Experiments; Quasi-Experimental Designs; Experimental Design: Large-Scale Social Experimentation).

Instrumental variables estimation is often used in an effort to solve an endogeneity problem. When an instrumental variables approach is used, aspects of the clustering problem may be sacrificed to solve what is perceived as a much more important one – selection into contexts. In eqn [3] replace X by T, suppose that the underlying data structure is quasi-experimental, and let $T_{ij} = 1$ if an individual is treated (0 otherwise). If Y is a health outcome and contexts are hospitals, and if assignment to treatment is not random, then s potentially contains unmeasured variables correlated with T and also with Y. In quasi- and nonexperimental data, whether a patient receives a particular kind of treatment can be nonrandom with some causes known, others not. An instrumental variables approach to this problem attempts to find one or more covariates W correlated with T and Y, where Y and W controlling T are uncorrelated, and W and ε are uncorrelated. It is often difficult to find plausible instruments (W), although contextual variables are sometimes used. Thus, instrumental variables estimation cannot be employed with the automaticity of any of the other approaches to clustered data.

Examples

An example of a Gaussian application, and another of a binary response application, illustrate the kinds of differences in

findings that can occur using alternative multilevel approaches. The data are from a 1% clustered sample of the 1990 Census of China, and are specific to Hainan Province. Clustering is at the enumeration district level, and within clusters enumeration is 100%.

Gaussian Example

In the Gaussian example, there are 17 662 men in the data, distributed over 332 clusters, the smallest having 114 men and the largest having 3735 men. The occupational socioeconomic status (SEI) of men of ages 20–65 is a function of age and years of schooling at the individual level, type of place of residence (rural vs urban), and the square of a contextualized measure of education. Type of place of residence is a characterization of place, and constant within contexts. Substantive theory and exploratory data analysis lead to this random effects model:

$$\begin{aligned} SEI &= \beta_{0j} + \beta_{1j}\text{Age} + \beta_{2j}\text{Ed} + \varepsilon \\ \beta_{0j} &= \eta_{00} + \eta_{01}\text{Rural} + \alpha_{0j} \\ \beta_{1j} &= \eta_{10} + \eta_{11}\text{CED}^2 + \alpha_{1j} \\ \beta_{2j} &= \eta_{20} + \eta_{21}\text{CED}^2 + \alpha_{2j} \end{aligned} \quad [7]$$

Table 1 reports coefficient estimates and ratios of coefficients to standard errors ('t-ratios') for several approaches. Regressions (1)–(3) are the same ordinary least squares (OLS) regression, differentiated to keep track of the type of standard error. When clustering is ignored, the t-ratios are far larger (regressions (1) and (2)). Unstructured adjustment of standard errors makes little difference. Adjusting OLS standard errors for clustering radically reduces the t-ratios (regression (3)). The fixed effects coefficients (regression (4)) are roughly the same as the OLS coefficients, with larger t-ratios than obtained with the clustering adjustment. Only one term is 'significant' when the clustering adjustment is used, whereas three of the four estimable coefficients are highly 'significant' in the fixed effects model. The coefficients of the random effects model (regression (5)) are comparable with those for the fixed effects model (where present), but the t-ratios are smaller. For those terms present in both the fixed effects and random coefficient models, coefficients are either significant in both models, or not significant in both. In computations not displayed here, the random coefficient specification was computed twice within two different programs, once using maximum likelihood and restricted maximum likelihood. There was an agreement across programs and methods. Although the basic conclusion is the same for the fixed effects and random coefficient models and differs somewhat from that provided by the clustering adjustment, the variation in coefficient magnitudes and t-ratios across the models is cautionary. Even in the Gaussian case, it can be misleading to estimate a model using only one approach.

Binary Response Example

In the binary response example, data from the 1990 Hainan sample are again used. Infants and toddlers born in the 18 months prior to the starting date of the Census enumeration are the level-1 units of observation, and enumeration districts are level-2 observations. The available data do not record child mortality, which has been inferred from maternal information elicited in the Census questionnaire. The response variable is whether an imputed death to a child born after 1988 occurred prior to 1 July 1990. There are 43 imputed deaths out of 2572 mother–child pairs. A majority of enumeration districts have no imputed deaths. For this reason, only the within-context intercept is treated as random. For ω, the logit of a death within the first 18 months of life, the specification treats the

probability of death as a function of maternal years of schooling, the sex of the child, and the interaction between maternal education and sex of child. The intercept is treated as a function of type of place of residence (the same for all residents of an enumeration district) and a random error:

$$\begin{aligned} \omega_{ij} &= \beta_{0j} + \beta_1 \mathrm{Ed} + \beta_2 \mathrm{Male} + \beta_3 \mathrm{Ed} \cdot \mathrm{Male} \\ \beta_{0j} &= \eta_{00} + \eta_{01} \mathrm{Rural} + \alpha_{0j} \end{aligned} \quad [8]$$

Table 2 presents a selection of regressions based on alternative multilevel approaches and algorithms. Regression (1) is the result of classical maximum likelihood estimation followed by an adjustment for clustering. Using this approach, neither the sex of the child nor the sex-education interaction is 'significant.' Using the GEE approach, the coefficient for sex is at the cusp of conventional significance and the sex-education interaction is significant (regression (2)). The fixed effects results, using conditional logistic regression, indicate significance for all included terms (regression (3)). Penalized quasi-likelihood estimates are provided by regression (4). These are consistent with the fixed effects results for those terms present across the fixed and random effects specifications. Regression (5) presents Bayesian results based on MCMC. The type of place of residence coefficient is smallest and not significant in the Bayesian regression. Application of a clustering adjustment to the GEE results (not shown) also substantially affects conclusions about statistical significance.

It is not unusual to encounter sparse data. This binary response example is perhaps even more cautionary than the Gaussian example. Researchers are not yet routinely able to determine whether convergence is to a local or global maximum, whether sufficient iterations have been calculated using MCMC, whether all of the assumptions required for a particular method are valid in a given instance, or whether software is performing as intended.

Conclusions

Analysis of multilevel data structures using methods that ignore the clustering of observations in the data is unsatisfactory because it can lead to confidence intervals that are too narrow, and to coefficient bias. Random coefficient models – and their specializations and generalizations – are attractive tools for the analysis of multilevel data. When there is selection into contexts, the random coefficient approach is subject to coefficient bias, as it is more generally when there are omitted regressors at any level. The fixed effects approach provides one kind of solution to the omitted variables problem. Instrumental variable estimation offers another. A posterior adjustment to accommodate clustering, applied to the estimated variances of coefficients, is robust but inefficient when the random effects model is correct. Although this adjustment does not require orthogonality between errors and covariates, robust standard errors for biased coefficients are far from universally desirable. For discrete and count responses, marginal models estimated using GEE provide an alternative to random effects models. Marginal models are attractive when there is little interest in within-context estimates, or when the pattern of within-context correlation is not simple. The choice of a multilevel modeling approach is ideally governed by research goals, the study design, and the nature of the data. There is also value in cross-checking results across methods and software.

Further Reading

For an introduction to random coefficient models (terminology often used interchangeably with random effects models and hierarchical models), see Snijders and Bosker (1999). The level of exposition in Bryk and Raudenbush (1992) ranges from introductory to advanced, as is also true for Goldstein (1995). The exposition in Longford (1993) is technically demanding. Littell et al. (1996) survey mixed models in general, and include material on hierarchical models. Gilks et al. (1998) and Gelman et al. (2013) are useful for Bayesian random coefficient models. Draper (2002) provides a detailed introduction to random coefficient models from the Bayesian perspective.

Fixed effects modeling is treated in econometrics texts (e.g., Greene, 2000), and is often discussed as one approach to the analysis of panel data (Baltagi, 1995). For the binary response case, see Pendergast et al. (1996), who provide a review with broad scope. Robust adjustments of standard errors for

clustering (e.g., Rogers, 1993) are an extension of the methodology of Huber (1967) and White (1980, 1982). The GEE approach is well exposited in Diggle et al. (1994), who provide detailed comparisons with random coefficient and other models. In this same vein, Allison's (1999) introduction should not be missed. Instrumental variables estimation is a standard subject in econometrics texts (e.g., Greene, 2000).

For an illuminating use of random coefficient models in the study of neighborhoods, see Sampson et al. (1997). Geronimus and Korenman (1992) use a fixed effects approach in the study of teen pregnancy. Hamilton and Hamilton (1997) use a fixed effects approach in the analysis of surgery outcomes. For the same kind of problem, but using a different data structure, McClellan et al. (1994) employ an instrumental variables approach. Applications of marginal models are found largely in the epidemiological and biomedical literature. Multilevel analysis has long been mainstream in economics, and will soon become so in the rest of the social sciences.

Software

Dedicated random coefficient packages include HLM5 (Raudenbush et al., 2000) and MLwiN (Goldstein et al., 1998). HLM5 additionally offers GEE estimation; MLwiN includes Bayesian MCMC estimation. Most major statistical packages include facilities for all of the approaches discussed here, as integral components or contributed macros. Software for multilevel analysis is in continuous development. The multilevel models mail list is an essential portal for current information (multilevel@jiscmail.ac.uk), as is the Web site hosted by the Multilevel Models Project (http://www.ioe.ac.uk/multilevel/).

Abstract

Outliers, or outlying observations, are values in data which appear aberrant or unrepresentative. They occur commonly and have to be dealt with. Unless an outlier is explainable, e.g., as a mis-recording, action must be based on the discrepancy between it and the model for the data. If a test shows the outlier to be inconsistent with the model, it is characterized as discordant. A discordant outlier may be identified as of intrinsic interest, rejected as a nuisance item, or incorporated in the main data via a revised model. Multiple outliers may be tested either one at a time, testing continuing so long as successive values are found discordant, or en bloc. The phenomena of masking and swamping are described. A main alternative to detecting and testing outliers is accommodation. Inference procedures are used which down-weight extreme values automatically, without regard to whether or not they are discordant. In complex situations such as regression on several variables, designed experiments, multivariate data, and multilevel data, a data point may be inconsistent with the pattern of the main data, and thus outlying, but not perceivable by inspection. Such an outlier is detectable by a statistical examination of residuals.

Anyone analyzing data may expect sometimes to encounter one or more observed values which appear to be inconsistent or out of line with the rest of the data. Such a value is called an outlying observation or outlier. Judged subjectively, it looks discrepant or surprising. There are two main ways of dealing with outliers, discordancy testing (Sections Outliers in Univariate Samples, Multiple Outliers: Block and Consecutive Tests) and accommodation (Section Accommodation of Outliers). In simpler types of data set, the presence of an outlier is evident by inspection. In more complex data situations such as designed experiments, an outlying observation may disrupt the expected pattern of results, though its presence is not obvious by inspection and a statistical procedure is needed to detect it (Section Outliers in More Complex Data Situations).

Two Simple Examples

A Disputed Paternity Case

In 1921 Mrs Kathleen Gaskill was sued for divorce in the British courts by her husband, a serving soldier, because she had given birth to a child 331 days after he had left the country to serve abroad. He claimed that the child could not be his, since 331 days was not credible as a duration of pregnancy. She denied adultery and claimed, with medical support, that the length of pregnancy, though unusual, was genuine. Viewed as a duration of pregnancy, 331 days is an outlier. In the legal case (which the court decided in favor of the wife), the only evidence of the alleged adultery was the abnormal length of this duration. This exemplifies the situation where the judgment of an outlier depends purely on its position in relation to a main data set. Table 1 gives the durations of pregnancy for 1669 women who gave birth in a maternity hospital in the north of England in 1954 (summarized from Newell, 1964). Clearly 331 days, exceeded certainly by 1 case and possibly by 2 out of 1669 in this data set, cannot be regarded as an incredible duration.

Predicting College Grades

Figure 1 shows a scatter plot of points (x, y) for a small sample of 22 college students; x is the student's score in an aptitude test, used as a predictor of college performance, and y is the student's freshman year grade-point average. There are two

Figure 1 Scatter plot of grade-point average y vs predictive test score x for 22 college students.

Table 1 Durations of pregnancy for 1669 women

Duration (weeks)	*11–20*	*21–25*	*26–30*	*31–35*	*36–38*	*39–41*	*42*	*43*	*44*	*45*	*46*	*47*	*56*

outlying points A(x_A, y_A) and B(x_B, y_B); the desired predictive relationship of y from x could be modeled satisfactorily by a linear regression omitting these two points. Should they be included in the relationship or not? This is discussed in Section Outliers in More Complex Data Situations. *See* Linear Hypothesis: Regression (Basics).

Outliers in Univariate Samples

The nature of outliers and the range of issues in dealing with them are first discussed in the simple situation of a univariate sample of n observations $x_1, x_2, \ldots, x_n$ of a variable X. Denote the observations arranged in ascending order by $x_{(1)}, x_{(2)}, \ldots, x_{(n)}$, $x_{(1)} < x_{(2)} < \cdots < x_{(n)}$. If, say, the upper extreme observation $x_{(n)}$ appears (to an analyst or investigator examining the data) to be, not only higher than the rest of the sample but surprisingly high, it is declared an outlier. This is a subjective judgment. Is the outlier credible as a value of X? This depends on the form the investigator is assuming for the distribution of X, e.g., whether it is, say, normal or on the other hand a skew distribution such as exponential in which a high value $x_{(n)}$ is less surprising. Call this assumed model for the distribution of X the basic model and denote it by F; $x_{(n)}$ is an outlier relative to model F (e.g., normal), but may not be an outlier relative to a different model (e.g., exponential).

Table 2, with dotplot Figure 2, gives the scores by 30 children in a reading accuracy test. There is an upper outlier $x_{(30)} = 62$ and possibly a second one $x_{(29)} = 53$. The variable X is here the reading accuracy test score obtained by a child in a population of children of the relevant age group and educational characteristics. A reasonable working assumption is that its distribution is normal; this is supported by a plot of ordered values against normal order scores, which is roughly linear.

Causes of Outliers

No statistical issue arises if there is a tangible explanation for the presence of an outlier, e.g., if in the above example the score was misrecorded, or component subscores were wrongly totaled, or if the child tested was known to be unrepresentative of the population under study. The outlying value would simply be removed from the data set, or corrected where appropriate, e.g., in the case of wrong totaling.

Otherwise, a statistical judgment is required for interpreting the outlier and deciding how to deal with it, based on the apparent discrepancy between it and the pattern the investigator has in mind for the data – the basic model F. This judgment requires a test of the null hypothesis or working hypothesis H that all n observations belong to F. On this hypothesis, the upper outlier $x_{(n)}$ is a value from the distribution of a variable $X_{(n)}$, the highest observation in a random sample of size n from F. If H is rejected by a statistical test at

Figure 2 Dotplot of the 30 test scores in Table 2.

some level (e.g., 5 percent), $x_{(n)}$ is judged to be not credible (at the level of the test) as the highest value in a sample of size n from F. It is then said to be a discordant outlier (relative to the basic model F); the test of H is a discordancy test. (*See* Hypothesis Testing in Statistics; Significance, Tests of. See also Section Other Meanings of the Word 'Outlier'.).

In a Bayesian approach, there is no direct analogue of a test of discordancy. Its place is taken by procedures designed to obtain a posterior probability assessment of the 'degree of contamination' of the data. This means the degree to which the data contain observations ('contaminants') generated not by F but by some other model G; a basic model is used which contains additional parameters relating to a possible G (*see* Bayesian Statistics).

Treatment of Outliers: Retention, Identification, Rejection, Incorporation

If the result of the test is to accept H and find $x_{(n)}$ non-discordant, all the data can be taken to come from F, including the outlier. Although it has been thought to look somewhat unusual, it is consistent with having arisen purely by chance under the basic model and can be retained in the data set.

When on the other hand the outlier is adjudged discordant, there are three possibilities.

If the focus of interest is the outlier itself (as in the disputed paternity case), it is identified as a positive item of information, inviting interpretation or further examination; it might reveal, for instance, a novel teaching method causing an exceptional test score.

The other two possibilities, rejection and incorporation, arise when the investigator's concern is with the main data set, and the aim of the research is to study characteristics of the underlying population, e.g., to estimate the mean of a distribution of examination scores. The outlier is only of concern insofar as it affects these inferences about the underlying population. It is not of interest in itself; for example, the students giving rise to points A and B in Figure 1 are effectively unknown!

Either the model F is firmly adopted without challenge, and estimates or tests of the population parameters are to be based on F; or there is the option of changing the model.

If the model is not under question and inferences are to be based on it, the outlier, being adjudged inconsistent with F, is a nuisance item and should be rejected. Historically, outlying values have been studied since the mid eighteenth century,

Table 2 Reading accuracy test scores (in ascending order) for 30 children

2	4	5	8	9	12	12	12	12	14	16	16	18	19	20	21	23	23
23	26	27	27	28	30	34	38	40	42	53	62						

often in the context of astronomical observations. Until the 1870s rejection was often the only procedure envisaged for dealing with outliers, as typified by such publications as Peirce (1852) 'Criterion for the rejection of doubtful observations' and Stone (1868) 'On the rejection of discordant observations.'

The fact that an outlier is omitted for purposes of analyzing a data set does not necessarily mean that it is erroneous or undesirable. Consider, for example, Figure 3. The ordinates are annual figures for the population of the UK, in millions, published in each year's *Annual Abstract of Statistics*. Those for 1985 through 1990 are estimates based on the 1981 census, while the outlier at 1991, the true value from the 1991 census, is the only genuine data point!

The alternative possibility, when the outlier is adjudged discordant relative to F, is that all the observations, including the outlier, belong to the same distribution, but this distribution is not satisfactorily represented by the initial basic model F. The analysis then needs to start afresh with a more appropriate choice of model F* (e.g., a skew distribution instead of a symmetrical F), in relation to which $x_{(n)}$ is not discordant. It was an outlier relative to F, but is not an outlier relative to F*, which satisfactorily models the entire data set. It has been incorporated in the data set in a non-discordant fashion, and the outlier problem disappears.

Other Meanings of the Word 'Outlier'

In the entry, an observation which appears inconsistent with the main data set is called an outlier; this is a subjective judgment. If a statistical test provides evidence that it cannot reasonably be regarded as consistent with the main data set, it is a discordant outlier. It is important to bear in mind, however, that some writers use the word 'outlier' for a discordant outlier, and refer to an observation which looks anomalous but may or may not be discordant as a 'suspicious' or 'suspect' value.

Note also the different meaning given to the word 'outlier' in graphical displays in exploratory data analysis (EDA), such as boxplots. With Q_1 and Q_3 denoting (essentially) the lower and upper quartiles in the sample, observations greater than $Q_3 + k(Q_3 - Q_1)$ or less than $Q_1 - k(Q_3 - Q_1)$ are flagged as outliers. These values are sometimes outliers and sometimes not. With the typical value of 1.5 for k, a normal sample of size 100 has more than 50 percent chance of containing one or more of these 'outliers'! (*See* Exploratory Data Analysis: Univariate Methods).

Figure 3 Some annual figures for the UK population.

Multiple Outliers: Block and Consecutive Tests

Any particular discordancy test (taking univariate samples as context) is specified by three items: the particular outlier configuration (e.g., a lower outlier; an upper and lower outlier pair), the distribution of the data on the working hypothesis (e.g., normal with unknown mean and variance), and the test statistic. Taking Table 2 for illustration, there is a discordancy test for $x_{(30)} = 62$, in a normal sample, based on its difference from the sample mean $\bar{x} = 22.53$ in relation to the sample standard deviation $s = 14.13$, with test statistic $T = (x_{(n)} - \bar{x})/s = (62 - 22.53)/14.13 = 2.79$.

For $n = 30$ the tabulated 5 percent point of T on hypothesis H is 2.74; 62 is declared discordant (just) at the 5 percent level. The observation $x_{(29)} = 53$, which is also high, can now be tested for discordancy in relation to the other 28 values; this is a consecutive test procedure for 2 outliers. The value of T is (53–21.17) / 12.22 = 2.61, P≃8 percent, the evidence of discordancy is weak.

Alternatively, 62 and 53 could be considered together as an outlying pair in relation to the other 28 observations. This can be tested, in a block test procedure for 2 outliers, by the statistic $(x_{(n-1)} + x_{(n)} - 2\bar{x})/s$, which here $= (53 + 62 - 2 \times 22.53)$ / 14.13 = 4.95, to be compared with the tabulated 1 percent point 4.92. So, on this block test, there is quite strong evidence that (62, 53) are a discordant pair.

Masking and Swamping

If $x_{(29)}$ were nearer to $x_{(28)} = 42$, the T-value for $x_{(30)}$ would be higher than 2.79, and the evidence for the discordancy of $x_{(30)}$ would be stronger. This is called the masking effect. A discordancy test of the most extreme observation is rendered insensitive by the nearness of the next most extreme observation; the second observation has masked the first.

Conversely, a block test could be insensitive if the second observation $x_{(n-1)}$ is close to $x_{(n-2)}$ and not outlying. The pair $x_{(n)}$, $x_{(n-1)}$ might not reach discordancy level when tested jointly, even though $x_{(n)}$ on its own is discordant in relation to the other $n - 1$ observations. This is called the swamping effect of $x_{(n-1)}$. If $x_{(n-1)}$ is unduly high, there is the risk of masking; if it is unduly low, there is the risk of swamping.

Accommodation of Outliers

When the aim is to make inferences about a population of values of a variable X by analyzing a sample of observations of X, there is an alternative to detecting outliers and testing them for discordancy. This is to use procedures (testing or estimation) which are relatively unaffected by possible outliers, by giving extreme values less weight than the rest of the observations, whether they are discordant or not. Such a procedure is called robust against the presence of outliers (*see* Robustness).

There is a great range of procedures available in the literature. The approach is well illustrated by the following simple methods for robust estimation of the mean and variance of a univariate sample $x_{(1)} < x_{(2)} < \cdots < x_{(n)}$.

Trimming

The mean is calculated after one or more extreme values have been omitted from the sample. Omission of the r (lowest) and the s (highest) values gives the (r, s)-fold trimmed mean

$$\left(x_{(r+1)} + x_{(r+2)} + \cdots + x_{(n-s)}\right)/(n - r - s).$$

Winsorizing

Instead of omitting the r (lowest) values $x_{(1)},\ldots, x_{(r)}$, they are each replaced by the nearest value which is retained unchanged, i.e., $x_{(r+1)}$; similarly for the s (highest) values. The mean of the resulting modified sample, still of size n, is the (r, s)-fold Winsorized mean

$$\left((r+1)x_{(r+1)} + x_{(r+2)} + \cdots + x_{(n-s-1)} + (s+1)x_{(n-s)}\right)/n.$$

The choice of r and s depends on various factors such as the form of the distribution of X (e.g., symmetrical or asymmetrical) and the level of robustness required. The greatest possible amount of trimming or Winsorizing, with $r = s$, gives the sample median.

Robust estimates of variance can be based in various ways on the deviations $x - m$, where m is a trimmed or Winsorized mean, instead of the usual $x - \bar{x}$.

For an extensive account of accommodation issues and procedures, see Barnett and Lewis (1994).

Outliers in More Complex Data Situations

In a regression of a variable y on a single regressor variable x, an outlying point is apparent by inspection, as instanced by **Figure 1**. For a regression on 2 or more regressor variables x_1, $x_2,\ldots$, this is no longer the case. The data may nonetheless contain an outlying point (or more than one), i.e., a point (x, y) which departs to a surprising degree from the overall pattern of the data. Its observed response value y deviates 'surprisingly' from the fitted value from the regression equation; in other words, it has an outlying residual. Detection of an outlying point requires essentially a statistical examination of residuals.

To illustrate this, consider the regression data in **Figure 1**, with two outlying points A and B. Denote the fitted regression line CD by $y = a + bx (a = -1.528, b = 0.003528)$, with residual mean square $s^2 = 0.148$. The residual for the outlying point A is $y_A - (a + bx_A) = 1.4 - 2.447 = -1.047$, and its estimated standard deviation is

$$s\sqrt{\left\{1 - \frac{1}{n} - \frac{(x_A - \bar{x})^2}{\sum (x - \bar{x})^2}\right\}} = 0.371.$$

A discordancy test statistic for the point A is its studentized residual (the residual divided by its estimated standard deviation), viz. $-1.047 / 0.371 = -2.82$; this is just significant at the 5 percent level. On a similar test the outlying point B is not discordant at all. The most outlying point in the regression (in this case, A) is the one with the largest studentized residual, ignoring sign. *See* Linear Hypothesis: Regression (Basics).

An equivalent criterion to the studentized residual for testing discordancy is the proportional reduction in the residual sum of squares when the outlier is omitted, or, equivalently again, the increase in the maximized log-likelihood. The test then reflects directly how much the fit of the regression model to the data is improved on omission of the outlier. This approach – the deletion method – obviously extends to the detection and testing of multiple outliers, with the choice between block and consecutive deletion (*see* Likelihood in Statistics). It is also the appropriate approach to outliers in multivariate data; *see* Multivariate Analysis: Discrete Variables (Overview).

Similar considerations apply to the detection and testing of outliers in designed experiments and outliers in contingency tables, with use of residual-based or deletion procedures. *See* Experimental Design: Overview. Accommodation procedures are also available in the literature. Outliers also occur in time series (*see* Time Series: General). For details of methods for dealing with outliers in the various data situations mentioned above, see Barnett and Lewis, 1994.

Some work has been done on outliers in sample surveys, but the methodology for outliers in this vital field urgently needs developing. *See* Sample Surveys: Model-based Approaches.

In multilevel, or hierarchical, data the concept of an outlier becomes more complex, and much work needs to be done. *See* Hierarchical Models: Random and Fixed Effects; Statistical Analysis: Multilevel Methods; Lewis and Langford (2001). See also Langford and Lewis (1998), from which the following passage is quoted:

In a simple educational example, we may have data on examination results in a two-level structure with students nested within schools, and either students or schools may be considered as being outliers at their respective levels in the model. Suppose ... that ... a particular school is found under test to be a discordant outlier; we ... need to ascertain whether it is discordant owing to a systematic difference affecting all the students measured within that school or because one or two students are responsible for the discrepancy. At student level, an individual may be outlying with respect to the overall relationships found across all schools or be unusual only in the context of his or her particular school. ... [Again,] masking see Section Masking and Swamping can apply across the levels of a model. The outlying nature of a school may be masked because of another similarly outlying school or by the presence of a small number of students within the school whose influence brings the overall relationships within that school closer to the average for all schools.

Conclusion

'The concern over outliers is old and undoubtedly dates back to the first attempt to base conclusions on a set of statistical data .... The literature on outliers is vast ... ' (Beckman and Cook, 1983). As this article has shown, outliers occur commonly in data and the problem of how to deal with them

in any particular case is an unavoidable one. A massive armory of principle, model, and method has built up over the years. For a review of the relevant literature, see the extensive coverage of outlier methodology by Barnett and Lewis (1994), whose book, which includes some 970 references, still remains the only comprehensive treatment of the subject. A valuable survey of many outlier problems is also given in Beckman and Cook (1983).

Abstract

Statistical methods assist in classification in four ways: in devising probability models for data and classes so that probable classifications for a given set of data can be identified; in developing tests of validity of particular classes produced by a classification scheme; in comparing different classification schemes for effectiveness; and in expanding the search for optimal classifications by probabilistic search strategies. Standard hierarchical and partitioning algorithms are evaluated from a statistical point of view, and some improvements of these algorithms using density estimation methods and mixture models are proposed. Methods are given for identifying multimodality in high dimensional data.

Every formal inquiry begins with a definition of the objects of the inquiry and of the terms to be used in the inquiry, a *classification* of objects and operations. Since about 1950, a variety of simple explicit classification methods, called clustering methods, have been proposed for different standard types of data. Most of these methods have no formal probabilistic underpinnings. And indeed, classification is not a subset of statistics; data collection, probability models, and data analysis all require informal subjective prior classifications. For example, in data analysis, some kind of binning or selection operation is performed prior to a formal statistical analysis.

However, statistical methods can assist in classification in four ways.

1. In devising probability models for data and classes so that probable classifications for a given set of data can be identified;
2. In developing tests of validity of particular classes produced by a classification scheme;
3. In comparing different classification schemes for effectiveness; and
4. In expanding the search for optimal classifications by probabilistic search strategies.

These statistical methods are referred to as *cluster analysis* or *statistical classification*. The second term is preferred because a cluster, from its origin, tends to connote a crowd of points close together in space, but a class is a set of objects assembled together for any kind of reason, and so the more general term *classification* is to be preferred. Part of the reason for the narrower term *cluster analysis* is that the term *classification* was once used in statistics to refer to *discriminant analysis* (*see* Multivariate Analysis: Classification and Discrimination). In discriminant analysis, a classification rule is developed for placing a multivariate observation into one of a number of established classes, using the joint distribution of the observations and classes. These problems are regression problems: the variable to be predicted is the class of the observations. For example, logistic regression is a method for discriminant analysis with two classes. More recently, classification in statistics has come to refer to the more general problem of constructing families of classes, a usage which has always been accepted outside of statistics.

Algorithms

The first book on modern clustering techniques is by Sokal and Sneath (1963). The most comprehensive recent review of a huge diverse literature is Arabie et al. (1996) which includes in particular an excellent survey of algorithms by Arabie and Hubert and of probabilistic methods by Bock.

A classification consists of a set of classes; formal clustering techniques have been mainly devoted to either *partitions* or *hierarchical clustering* (see, however, the nonhierarchic structures in Jardine and Sibson, 1968; and the block clusters in Hartigan, 1975).

Partitions

A partition is a family of *classes*, sets of objects with the property that each object lies in exactly one class of the partition. *Ideal-object* partitions are constructed as follows. Begin with a set of given objects, a class of ideal objects, and a numerical dissimilarity between any given object and any ideal object. A fitted ideal object is associated with each class having minimum sum of dissimilarities to all given objects in the class.

The algorithm aims to determine k ideal objects, and a partition of the objects into k classes, so that the dissimilarity between an object and the fitted ideal object of its class, summed over all objects, is minimized. The usefulness of such a clustering is that the original set of objects is reduced with small loss of information to the smaller set of fitted ideal objects. Except in special circumstances, it is impracticable to search over all possible partitions to minimize the sum of dissimilarities; rather some kind of local optimization is used instead.

For example, begin with some starting partition, perhaps chosen randomly. First fit the ideal objects for a given partition. Second reallocate each object to the class of the fitted ideal object with which it has smallest dissimilarity. Repeat these two steps until no further reallocation takes place. The *k-means*

algorithm, MacQueen (1967), is the best known algorithm of this type; each object is represented by a point in p-dimensional space, the dissimilarity between any two points is squared Euclidean distance, and the ideal object for each class is the centroid of the class. Asymptotic behavior of the k-means algorithm is described in Pollard (1981).

Hierarchical Clustering

Hierarchical clustering constructs *trees* of clusters of objects, in which any two clusters are disjoint, or one includes the other. The cluster of all objects is the root of the tree.

Agglomerative algorithms, Lance and Williams (1967), require a definition of dissimilarity between clusters; the most common ones are *maximum or complete linkage*, in which the dissimilarity between two clusters is the maximum of all pairs of dissimilarities between pairs of points in the different clusters; *minimum or single linkage or nearest neighbor*, Florek et al. (1951), in which the dissimilarity between two clusters is the minimum over all those pairs of dissimilarities; and *average linkage* in which the dissimilarity between the two clusters is the average, or suitably weighted average, over all those pairs of dissimilarities.

Agglomerative algorithms begin with an initial set of singleton clusters consisting of all the objects; proceed by *agglomerating* the pair of clusters of minimum dissimilarity to obtain a new cluster, removing the two clusters combined from further consideration; and repeat this agglomeration step until a single cluster containing all the observations is obtained. The set of clusters obtained along the way forms a hierarchical clustering.

Object Trees

A different kind of tree structure for classification is a graph on the objects in which pairs of objects are linked in such a way that there is a unique sequence of links connecting any pair of objects. The *minimum spanning tree*, Kruskal (1956), is such a graph, constructed so that the total length of links in the tree is minimized. There may be more than one such optimal graph. The minimum spanning tree is related to single linkage clusters: begin by removing the largest link, and note the two sets of objects that are connected by the remaining links, continue removing links in order of size, noting at each stage the two new sets of objects connected by the remaining links. The family of connected sets obtained throughout the removal process constitutes the single linkage clusters.

In a Wagner tree, the given objects are end nodes of the tree, and some set of *ideal* objects are the possible internal nodes of the tree. A Wagner tree for the given objects is a tree of minimum total length in which the given objects are end nodes and the internal objects are arbitrary. A Wagner tree is a minimum spanning tree on the set of all objects and the optimally placed internal nodes. This tree has application in evolutionary biology as the *most parsimonious* tree reaching the given objects (Fitch and Margoliash, 1967).

A third kind of tree structure arises from the CART algorithm of Breiman et al. (1984). This algorithm applies to regression problems in which a given target variable is predicted from a recursively constructed partition of the observation space; the prediction is constant within each member of the partition. If the predictors are numerical variables, the first choice in the recursion looks over all variables V and all cut-points a for each variable, generating the binary variables identifying observations where $V < a$. The binary predictor most correlated with the target variable divides the data set into two sets, and the same choice of division continues within each of the two sets, generating a *regression tree*. It is a difficult problem to know when to stop dividing. These regression trees constitute a classification of the data adapted to a particular purpose: the accurate prediction of a particular variable.

Usually, only the final partition is of interest in evaluating the regressive prediction, although the regression tree obtained along the way is used to decide which variables are most important in prediction, for example, the variables appearing in the higher levels of the tree are usually the most important. However, if there are several highly correlated variables, only one might appear in the regression tree, although each would be equally useful in prediction.

Probabilistic Classification

The aim is to select an appropriate classification C from some family Γ based on given data D

Mixture Models

It is assumed that there are a number of objects, denoted $x_1, \ldots, x_n$, which are to be classified. A probability model specifies the probability of an observation x when x is known to come from a class with parameter value θ, say $p(x|\theta)$. The parameter value θ corresponds to an ideal point in the partition algorithm (section 'Hierarchical Clustering'). The *mixture* model assumes that there is a fixed number of classes k, that an object x_i comes from class C_j with mixing probability p_j, so that the probability of observation x is $p(x) = \Sigma_j p_j p(x|\theta_j)$, and collectively the observations have probability $\Pi_i p(x_i)$. The parameters p_j and θ_j usually are estimated by maximum likelihood in a non-Bayesian approach. No single partition is produced by the algorithm, but rather the conditional probability of each partition at the maximum likelihood values of the parameters. How do these statistical partitionings compare with the dissimilarity based partitions of the section Hierarchical Clustering? Suppose the partition itself is a parameter to be estimated in the statistical model; estimate the optimal partition $C = \{C_1, \ldots, C_k\}$, and the parameter p_j, θ_j to maximize the probability of the data given the partition $\Pi_j \Pi_{x_i \in C_j} p_j p(x_i|\theta_j)$. Thus, the optimal partition in the statistical model is the optimal partition in a dissimilarity model with dissimilarities between the object x_i and the ideal object θ_j

$$d(x_i, \theta_j) = \log(p_j) + \log p(x_i|\theta_j) \qquad [1]$$

It is, thus, possible to translate back and forth between statistical models and dissimilarity models by taking dissimilarities to be log probabilities.

However, it is wrong to estimate the optimal partition by maximizing the probability of the data given the partition and

parameters over all choices of partitions and parameters; as the amount of data increases, the limiting optimal partition does not correspond to the *correct* partition obtained when the parameters p_j, θ_j are known. The correct partition assigns x_i to the class that maximizes $p_j p(x_i|\theta_j)$. In contrast, the estimate of p_j, θ_j that maximizes the data probability averaged over all possible partitions, is consistent for the true values under mild regularity conditions, and the partition determined from these maximum likelihood estimates is consistent for the correct partition.

In a Bayesian approach, the probability model is a joint probability distribution over all possible data D and classifications C. The answer to the classification problem is the conditional probability distribution over all possible classifications C given the present data D. Add to the previous assumptions a prior distribution on the unknown parameters p_j, θ_j (Bock, 1972). Again, consistent estimates of the correct classification are not obtained by finding the classification C and parameters p, θ of maximum posterior probability. Use the marginal posterior distribution of p, θ averaging over all classifications, to give consistent maximum posterior density estimates $\widehat{p}$, $\widehat{\theta}$ say. Then find the classification C of optimal posterior probability C given the data and given $p = \widehat{p}$, $\theta = \widehat{\theta}$. This classification will converge to the optimal classification for the mixture distribution with known p and θ.

If in addition a prior distribution is specified for the number of clusters, a complete final posterior distribution is available for all possible partitions into any number of components.

Hierarchical Models

Many of the hierarchical methods assume a dissimilarity function specifying a numerical dissimilarity $d(i, j)$ for each pair of objects i, j. If d satisfies the *ultrametric inequality* for every triple i, j, k

$$d(i,j) \leq \max[d(i,k), d(j,k)] \qquad [2]$$

then the various hierarchical algorithms discussed in the section 'Hierarchical Clustering' all produce the same clusters. The dissimilarity between a given object and another object in a given cluster C is less than the dissimilarity between that object and another object not in C. Thus hierarchical clustering may be viewed as approximating the given dissimilarity matrix by an ultrametric; methods have been proposed that search for a good approximation based on a measure of closeness between different dissimilarities.

With slightly more generality, *evolutionary distances* between a set of objects conform to a tree in which the objects are end nodes and the internal nodes are arbitrary. A nonnegative link distance is associated with each link of the tree, and the evolutionary distance between two objects is the sum of link distances on the path connecting them. Evolutionary distances are characterized by the following property: any four objects i, j, k, l may be partitioned into two pairs of objects in three ways; for some pairing (i, j), (k, l) say, the *evolutionary equality* is satisfied

$$d(i,k) + d(j,k) = d(i,l) + d(j,k) \qquad [3]$$

The pairing (i, j), (k, l) means that the tree path from i to j has no links in common with the tree path from k to l. We can construct an evolutionary tree on a set of objects by approximating a given dissimilarity by an evolutionary distance.

One case where evolutionary distances arise probabilistically is in the factor analysis model in which the objects to be classified form a set of v variables on which a number of independent v-dimensional observations have been made (Edwards and Cavalli-Sforza, 1964). The variables are taken to be end nodes in an evolutionary tree whose links and internal objects remain to be determined. Associated with each link of the tree is an independent normal variable with mean zero and variance depending on the link; this variance is the link distance. Each observation for the v variables is generated by assigning the random link values; then the variable $V_i - V_j$ is a sum of independent normal variables along the path of directed links connecting i and j. The random normal associated with each link is of opposite sign when the link is traversed in the opposite direction. The quantities $d(i, j) = E(V_i - V_j)^2$ form a set of evolutionary distances, which are estimated by $\widehat{d}(i,j) = \text{sample have } (V_i - V_j)^2$.

For each observation $\{V_1 - V_i, i = 2, \ldots p\}$ is multivariate normal with a covariance matrix determined by the link variances, and the log likelihood may be written, for a certain weight function w

$$\sum_{i,j} \left(\widehat{d}(i,j) - d(i,j)\right) w_{i,j}(\sigma) \qquad [4]$$

This expression is maximized to estimate the unknown σ values. In this case the sample distances form a sufficient statistic for the parameters, and no information is lost in using distances rather than the complete data set. Similar discrete Markovian models due to Felsenstein (1973) reconstruct evolutionary trees from DNA sequence data.

A nonparametric model for hierarchical clustering assumes that the objects $x_1, \ldots, x_n$ to be clustered are sampled randomly from a space with values $x \in S$ and density f with respect to some underlying measure, usually counting measure or Lebesgue measure. It is necessary to have a concept of connectedness in the space S. The family of connected sets of points having density $f(x) > c$, computed for each nonnegative c, together form a hierarchical clustering called *high density* clusters (Bock, 1974; Hartigan, 1975). The statistical approach estimates this hierarchical clustering on the density f from the given sample $x_1, \ldots, x_n$ by first estimating the density f by $\widehat{f}$ say, then forming the estimated clusters as the high density clusters in $\widehat{f}$. There are numerous parametric and nonparametric estimates of density available.

How do the standard hierarchical clustering methods do in estimating these high density clusters? Badly. The single linkage clusters may be reexpressed as the high density clusters obtained from the nearest-neighbor density estimator; the density estimate at point x is a decreasing function of $d(x, x_i)$, where x_i is the closest sample point to x. This estimator is inconsistent as an estimate of the density, and the high density clusters are correspondingly poorly estimated. However, it may be shown that the single linkage method is able to consistently identify distinct modes in the density. On the other hand, complete linkage corresponds to no kind of density estimate at all, and the clusters obtained from complete linkage are not consistent for anything at all, varying randomly as the amount of data

increases. In evaluating and comparing clustering methods, a statistical approach determines how well the various clustering methods recover some known clustering when data is generated according to some model based on the known clustering (Milligan, 1980). The most frequently used model is the multivariate normal mixture model.

Validity of Clusters

A typical agglomerative clustering produces $n - 1$ clusters for n objects, and different choices of dissimilarities and cluster combination rules will produce many different clusterings. It is necessary to decide 'which dissimilarity, which agglomeration method, and how many clusters'.

In partition problems, if a parametric mixture model is used, standard statistical procedures described in the section 'Mixture Models' are available to help decide how many components are necessary. These models require specific assumptions about the distribution within components that can be critical to the results. The nonparametric *high density* cluster model associates clusters with modes in the density. The question about number of clusters translates into a question about number of modes.

The *threshold or kernel width* test (Silverman, 1981) for the number of modes is based on a kernel density estimator, for example, given a measure of dissimilarity, and a threshold d, use the density estimate at each point x consisting of the sum of $1 - d(x, x_i)/d$ over observed objects x_i within dissimilarity d of x. The number of modes in the population is estimated by the number of modes in the density estimate. To decide whether or not two modes are indicated, the quantity d is increased until at $d = \widehat{d}_1$, the estimated density $\widehat{f}_1$ first has a single mode. If the value $\widehat{d}_1$ required to render the estimate unimodal is large enough, then more than one mode is necessary. To decide when $\widehat{d}_1$ is large, resample from the unimodal distribution $\widehat{f}_1$, obtaining a distribution of resampled $\widehat{d}_1$ values for those samples, the values of d in each of those resamples required to make the density estimate unimodal. The tail probability associated with the given $\widehat{d}_1$ is the proportion of resampled $\widehat{d}_1$ that exceed the given $\widehat{d}_1$. A similar procedure works for deciding whether or not a number of modes larger than 2 is justified. An alternative test that applies in one dimension for two modes versus one uses the DIP statistic (Hartigan and Hartigan, 1985), the maximum distance between the empirical distribution function and the unimodal distribution function that is closest to the empirical distribution function. The null distribution is based on sampling from the uniform.

Probabilistic Search

Consider searching for a classification C in a class Γ that will maximize $l(C)$, the log probability of C given the data. Γ is usually too large for a complete search, and a local optimization method is used. Define a neighborhood of classifications $N(C)$ for each classification C. Beginning with some initial classification C_0, steepest ascent selects C_i to be the neighbor of C_{i-1} that maximizes $l(C)$, and the algorithm terminates at C_m when no neighbor has greater probability. Of course, the local optimum depends on the initial classification C_0, and the local optimum will not in general be the global optimum.

The search may be widened probabilistically by *randomized steepest ascent or simulated annealing* (Klein and Dubes, 1989), as follows: rather than choosing C_i to maximize $l(C)$ in the neighborhood of C_{i-1}, choose C_i with probability proportional to $\exp(1(C)/\lambda)$ from the neighborhood of C_{i-1}. In running the algorithm, we keep track of the highest probability classification obtained to date, and may return to that classification to restart the search. The degree of randomness λ may be varied during the course of the search. To carry out randomized ascent at randomness λ add to the log probability of each classification the independent random quantity $-\lambda \log E$, where E is exponential; then do perform deterministic steepest ascent on the randomized criterion.

To be specific, consider the probabilification of the *k-means* algorithm, that constructs say k clusters of n objects in v dimensions to minimize the total within cluster sum of squares S. Use a probability model in which within cluster deviations are independent normal with variance σ^2, the cluster means are uniformly distributed, and σ^2 has density $\sigma^{-(2vk+4)}$ (these prior assumptions match maximum likelihood), the log probability of a particular classification into two clusters given the data is

$$-\left[\frac{1}{2}(n+1)vk+1\right]\log S \qquad [5]$$

Steepest ascent k-means switches between clusters the observation that most decreases S; randomized steepest ascent switches the observation that most increases the randomized criterion

$$-\left[\frac{1}{2}(n+1)vk+1\right]\log S - \lambda \log E \qquad [6]$$

Finally, to choose the number of clusters, allowing k to vary by permitting an observation to 'switch' to a new singleton cluster. Penalize against many clusters by the BIC penalty; the number of parameters (cluster means and the variance) specifying k clusters in v dimensions is $vk + 1$; so the final randomized criterion is

$$-\frac{1}{2}nvk \log S - \lambda \log E - \frac{1}{2}(vk+1)\log n \qquad [7]$$

This formula adjusts only for the increase in log probability due to selecting optimal parameter values, and not for the increase in the log probability caused by selecting the highest probability partitions. A number of alternative choices of information criterion are proposed by Bozdogan (1988).

Conclusion

Although probabilistic and statistical methods have much to offer classification, in providing formal methods of constructing classes, in validating those classes, in evaluating algorithms, and in spiffing up algorithms, it is important to realize that classifications have something to contribute to statistics and

probability as well. The early extensive development of taxonomies of animals and plants in Biology proceeded quite satisfactorily without any formal statistics or probability through 1950; the big methodological change occurred in the late-nineteenth century following Darwin, who demanded that biological classification should follow genealogy.

Classification is a primitive elementary basic form of representing knowledge that is prior to statistics and probability. Many of the standard algorithms were developed without allowing for uncertainty. Many of them, such as complete linkage, say, do not seem supportable by any statistical reasoning. Others will benefit by statistical evaluations and by probabilistic enhancements, as suggested in Hartigan (2000) and Gordon (2000).

Classification is both fundamental and subjective. If an observer classifies a set of objects to be in a class, for whatever reason, that class is valid in itself. Thus, there is no correct natural classification that our formal techniques can aim for, or that our statistical techniques can test for. Since classification is fundamental, it should be used to express formal knowledge, and probabilistic inferences and predictions should be based on these classificatory expressions of knowledge, Hartigan (2000). More formal and refined classifications may be assisted and facilitated by probability models reflecting and summarizing the prior fundamental classifications.

Abstract

The purpose of a one-sample test of fit is to give an objective measure of how well a probability model agrees with observed data. Here we discuss the test of Karl Pearson and derivatives of it, tests based on the empirical distribution function and the construction of the Neyman–Barton smooth tests. In the final section, we then address some modern developments in smooth testing: diagnostics, Cholesky components, data-driven tests and model selection. Other tests of fit, such as correlation tests and Laplace transform tests, are not considered here.

Introduction

The purpose of a one-sample test of fit is to give an objective assessment of how well a probability model agrees with observed data. Otherwise, as Pearson (1900: p. 171) said: "the comparison of observation and theory in general amounts to a remark – based on no quantitative criterion." Reviews of Pearson's paper may be found in Plackett (1983) and Rayner et al. (2009: Sect. 2.2). The multiple sample goodness of fit problem assesses whether data from a number of populations are consistent with having come from the same population. If the answer is affirmative, then the one-sample question may be appropriate. We will not consider the multiple sample problem here.

In many situations it will be valuable to find out if data for a particular event are consistent with an established pattern or model. Specifically, (1) can extreme events, such as flood heights, insurance losses, and equity risks be modeled by the extreme value distribution, (2) are right skewed data, that might arise, for example, in life testing and reliability contexts, consistent with the Rayleigh distribution, and (3) are data, usually binomial in similar scenarios but too overdispersed to be so in the current context, consistent with the beta-binomial? This sometimes occurs with taste test and market research data.

Rayner et al. (2009) identify three benefits of having applied a goodness of fit test:

- a compact description of the data;
- illumination of the data generation mechanisms; and
- validation or not of distributional assumptions necessary for the application of powerful parametric procedures.

The best of modern methods add another benefit: selection of a more valid model than that originally hypothesized.

Here we discuss tests for multinomial models, tests based on the empirical distribution function (EDF), and the construction of the Neyman–Barton smooth tests. In the final section we then address some modern developments in smooth testing: diagnostics, Cholesky components and model selection. Other tests of fit have been suggested, but we shall not consider these here, except to briefly mention two. Correlation tests are sometimes suggested in conjunction with quantile–quantile or probability plots of the data. The Shapiro–Wilk test of normality, for example, may be considered a correlation test. See D'Agostino and Stephens (1986). Tests based on the empirical Laplace transform are a general class of tests and often have competitive power. See, for example, Henze and Meintanis (2002, 2012).

Tests for Multinomial Models

For Pearson's test, sometimes called the Pearson chi-squared test, observations O_1, O_2, …, O_m are assumed to come from m nonoverlapping classes that are expected to contain E_1, E_2, …, E_m observations. The test statistic is

$$X_P^2 = \sum_{i=1}^{m} (O_i - E_i)^2 / E_i$$

Pearson (1900) assumed that parameters of the probability model giving rise to the cell expectations were known, and showed that the asymptotic distribution of X_P^2 is the χ^2_{m-1} distribution.

There is a considerable literature on how, when there is choice, the cells may best be constructed. The recommendation that for the χ^2 approximation to be adequate the cell expectation be at least five, goes back to Sir Ronald Fisher writing in the 1920s. This advice is now seen as extremely conservative.

Most interesting applications involve estimating parameters. Pearson incorrectly asserted that estimating parameters makes no difference to the asymptotic null distribution of the test statistic. If the cell expectations are calculated from parameters estimated efficiently from the grouped data, then Sir Ronald Fisher, again writing in the 1920s, showed that if q parameters are estimated from the grouped data using maximum likelihood the asymptotic distribution is χ^2_{m-q-1}. However, if estimation is via maximum likelihood using the ungrouped data Chernoff and Lehmann (1954) showed that Pearson's statistic no longer had an asymptotic chi-squared distribution. See Rayner et al. (2009) for a fuller discussion of cell construction and multinomial testing when parameters need to be estimated.

There are many possible generalizations of Pearson's test. Neyman's version is based on the test statistic

$$X_N^2 = \sum_{i=1}^{m} (O_i - E_i)^2 / O_i$$

One interesting possibility is the Cressie–Read family, based on the test statistic

$$I_\lambda = \frac{2}{\lambda(\lambda+1)} \sum_{i=1}^{m} O_i \left\{ \left(\frac{O_i}{E_i} \right)^\lambda - 1 \right\}$$

Taking $\lambda = 1$ leads to X_P^2, $\lambda = -1$ leads to a modified likelihood ratio statistic, $\lambda = 0$ is the usual likelihood ratio statistic, $\lambda = -0.5$ is the Freeman–Tukey statistic, and $\lambda = -2$ leads to X_N^2. Other choices can lead to tests with excellent properties; see Read and Cressie (1988).

EDF Tests

Much data are essentially continuous, and grouping it to permit the use of X_P^2 and other statistics based on the multinomial loses information and often power. A different approach that does not group the data is to compare the EDF with the distribution function specified by the hypothesized probability distribution. The Russian mathematician Kolmogorov (1933) proposed the first such test. EDF tests of fit, especially for continuous distributions, are reviewed in D'Agostino and Stephens (1986). Tests of fit for discrete distributions using the EDF approach are considered in Choulakian et al. (1994). See also Spinelli and Stephens (1997).

If we have n data points, the EDF $F_n(x)$ is given by

$$F_n(x) = (\text{number of observations } \leq x)/n$$

Tests of fit for a hypothesized distribution function, $F(x)$, can be made by looking at the difference between $F_n(x)$ and $F(x)$ for each data point. Kolmogorov (1933) suggested the statistic

$$\text{KS} = \max_x |F_n(x) - F(x)|$$

while a generally more powerful test is based on the Anderson and Darling (1954) statistic. Its calculation is illustrated in Example 1 below.

It can be shown that the EDF test statistics are linear combinations of components with decreasing weights. The components are similar to those defined in the following section on Neyman Smooth Tests. See, for example, Stephens (1974). If the null hypothesis specifies a discrete distribution where the number of classes is fixed and not too large (say five or less), we suggest calculating X_P^2 to assess goodness of fit. Otherwise, the Anderson–Darling test is a good choice, as it weights the important early components heavily and gives a powerful omnibus assessment.

Example 1: Testing Normality

Consider the following set of examination marks from 20 students:

53, 15, 70, 73, 79, 48, 91, 20, 24, 91, 87, 15, 3, 78, 78, 62, 16, 15, 20, 32.

Are these data normally distributed?

First we apply the Pearson–Fisher test with class boundaries –12.5, 12.5, 37.5, 62.5, 87.5, 112.5 and midpoints 0, 25, 50, 75, 100. The cell counts are 1, 8, 3, 6, 2. We find $X_{PF}^2 = 5.22$ with p-value 0.07 using the χ_2^2 distribution. The normality assumption would seem to be marginal.

We now apply the Anderson–Darling test. We calculate $\bar{x} = 48.5$ and $s = 30.8$ and then find $y_i = (x_i - \bar{x})/s$ for $i = 1, \ldots, 20$, where the x_i are the 20 exam marks. Next use a computer routine or tables of the standard normal distribution to find

$$z_i = F(y_i) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{y_i} \exp(-x^2/2)\mathrm{d}x$$

and order the z_i as $z_{(1)}, z_{(2)}, \ldots, z_{(n)}$. Then the Anderson–Darling statistic, AD say, is

$$\text{AD} = -n - n^{-1} \sum_{i=1}^{n} (2i-1) \left\{ \log z_{(i)} + \log z_{(n+1-i)} \right\}$$

which, for the above data, takes the value 0.931. From tables of critical values, such as D'Agostino and Stephens (1986: Table 4.9), or using MINITAB's Normplot routine, we find a p-value of 0.014. This implies the normality hypothesis is doubtful and the marks are not well summarized by $\bar{x} \pm s$. We revisit this example later.

Example 2: Testing the Poisson Assumption

Consider the number of people in a shopping mall contributing to a charity collector during 5-min intervals:

Number of contributors	0	1	2	3	4	5	6	7	8
Number of intervals	9	27	26	17	10	8	4	3	1

The sample size is $n = 105$. Let the observed and expected counts assuming a Poisson distribution be o_j and $e_j = np_j$, respectively, for $j = 0, 1, \ldots, 8$. Pooling cells from 7 onwards to get all cell expectations greater than one, we find $X_{PF}^2 = 8.62$ with p-value 0.20 using the χ_7^2 distribution. At all reasonable levels the Poisson assumption is acceptable.

Now let $z_j = \sum_{i=0}^{j} (o_i - e_i)$, in which case

$$\text{AD} = \frac{1}{n} \sum_{j=0}^{7} \frac{\hat{z}_j^2 \hat{p}_j}{\hat{h}_j \left(1 - \hat{h}_j\right)}$$

where the '^' indicates we have estimated the Poisson parameter by the sample mean. We find that AD = 1.178, and, using Spinelli and Stephens (1997: Table 1), the p-value is between 0.025 and 0.050. Thus the distribution is not well fitted by a Poisson model. It seems plausible that contributors come in clusters rather than at random, as a Poisson model would imply. The Pearson–Fisher test is far less critical of the Poisson assumption than the Anderson–Darling test.

Neyman Smooth Tests

One problem with Pearson's chi-squared test is that it is an omnibus test, with some power against general alternative

distributions to the hypothesized distribution, but with relatively poor power against important directional alternatives. Alternatives that are often of great practical importance are differences between the data and the mean, variance and, to a lesser extent, the skewness and kurtosis of the specified distribution. A test that does have good power at detecting these moment alternatives is Neyman's (1937) 'smooth' test. It has the useful property that it can readily be partitioned into *components* that give a powerful and detailed scrutiny of the data. See Rayner et al. (2009: Section 4.1) for a review of Neyman (1937).

The Neyman smooth tests may be applied to both categorized and uncategorized distributions and distributions that may or may not involve nuisance parameters. See Rayner and Best (1990) and Rayner et al. (2011) for overviews. Most modern authors use orthonormal functions, as did Neyman (1937), and permit nuisance parameters, contrary to Neyman (1937). The smooth tests may be used to test for very general distributions, provided orthonormal functions on the specified distribution may be constructed. Recurrence formulae for orthonormal polynomials are given for univariate distributions in Rayner et al. (2008) and for bivariate distributions in Rayner et al. (2013).

The test is based on the score statistic, and hence is weakly optimal, and the test statistic has a convenient asymptotic chi-squared distribution. In our preferred formulation components are readily available, and are asymptotically independent, each asymptotically having the standard normal distribution. The components are often the basis for well-known tests of fit in their own right, but more importantly, may permit a detailed, convenient and informative scrutiny of the data. The order of the test (see below) is at the user's discretion, and it may be chosen to give an omnibus or directional test, or something between.

Suppose we wish to test for a probability density function $f_X(x;\beta)$, where $\beta = (\beta_1, \ldots, \beta_q)^{\mathrm{T}}$ is a $q \times 1$ vector of parameters (such as μ and σ in the normal case). This null probability density function is nested in the order k probability density function

$$g_k^{\mathrm{N}}(x;\theta,\beta) = C(\theta,\beta)exp\left\{\sum_{i=1}^{k}\theta_i\pi_i(x;\beta)\right\}f_X(x;\beta)$$

(N is for Neyman) where $\theta = (\theta_1, \ldots, \theta_k)^T$ is a vector of k real parameters, $C(\theta, \beta)$ is a normalizing constant that is assumed to exist, and $\{\pi_i(x;\beta)\}$ is a set of functions orthonormal on $f_X(x;\beta)$ with $\pi_0(x;\beta) = 1$ for all x. Thus for $f_X(x;\beta)$ continuous,

$$\int_{-\infty}^{\infty}\pi_i(x;\beta)\pi_j(x;\beta)f_X(x;\beta)\mathrm{d}x = 1 \text{ for } i = j \text{ and zero otherwise.}$$

Sometimes $C(\theta, \beta)$ may not exist but the statistic we are about to define will. Using a random sample $X_1, \ldots, X_n$ we test for $f_X(x;\beta)$ parametrically, by testing H_0: $\theta = 0$ against K: $\theta \neq 0$, with β a vector of nuisance parameters. For small k the alternatives vary 'smoothly' from the null, in the sense of Neyman (1937). As an example of this, in testing for the standard normal distribution, the order one alternative is a normal distribution with a mean shift, the order two alternative is a normal distribution with both a mean shift and a variance shift, and the third order alternative is more involved, with mean, variance, and skewness differences from the hypothesized normal distribution.

Neyman (1937) developed this approach for the case of no nuisance parameters. In this situation the probability integral transformation converts the problem of testing for a completely specified distribution to testing for the uniform (0, 1) distribution. Thomas and Pierce (1979) and Kopecky and Pierce (1979) considered smooth tests for general distributions involving nuisance parameters. Their tests are based on a family of alternatives specified using powers of the cumulative distribution function rather than orthogonal polynomials as Neyman (1937) used, and as a consequence they require tables of coefficients for their implementation. Our preferred formulation permits nuisance parameters and uses orthonormal functions, thereby avoiding the need for tables of coefficients. For a more detailed account of the history of the smooth tests, see Rayner et al. (2009: Section 1.2).

When no nuisance parameters are present, the smooth test statistic based on the model $g_k^{\mathrm{N}}(x;\theta,\beta)$ is

$$S_k = V_1^2 + \ldots + V_k^2$$

in which the components V_r are given by

$$V_r = \sum_{j=1}^{n}\pi_i(X_j;\beta)\Big/\sqrt{n}$$

When testing for a distribution from an exponential family of distributions, such as the binomial, Poisson, geometric, or normal, the likelihood equations for $\widehat{\beta}$, the maximum likelihood estimator of β, are $\widehat{V}_r = V_r(\widehat{\beta}) = 0$ for $r = 1, \ldots, q$. The model $g_k^{\mathrm{N}}(x;\theta,\beta)$ results in a singular asymptotic covariance matrix for $(\widehat{V}_r)$. This can be resolved by removing $\theta_1, \ldots, \theta_q$ from the model, that is, by modifying $g_k^{\mathrm{N}}(x;\theta,\beta)$ to $C(\theta,\beta)exp\{\sum_{i=q+1}^{q+k}\theta_i\pi_i(x;\beta)\}f_X(x;\beta)$. What is happening here is that $\theta_1, \ldots, \theta_q$ are playing the same role as the elements of β, so the presence of all these parameters in the model leads to a redundancy. The test statistic is

$$\widehat{S}_k = \widehat{V}_{q+1}^2 + \ldots + \widehat{V}_{q+k}^2$$

in which $\widehat{V}_r = \sum_{j=1}^{n}\pi_i(X_j;\widehat{\beta})/\sqrt{n}$.

When testing for a distribution outside of an exponential family the score test statistic is not a simple sum of squares: it is a quadratic form. This will be considered in the next section.

It may occur that in $g_k^{\mathrm{N}}(x;\theta,\beta)$ a normalizing constant $C(\theta, \beta)$ cannot be found. An alternative smooth model is due to Barton (1953, 1955, 1956):

$$g_k^{B}(x;\theta,\beta) = \left\{1 + \sum_{i=1}^{k}\theta_i h_i(x;\beta)\right\}f(x;\beta)$$

(B is for Barton). These densities do not require the existence of the normalizing constant, but may be negative. This negativity may be handled using adjustments, such as those proposed in Gajek (1986) and in Glad et al. (2003), but this is only a problem for nonparametric density estimation and not for the smooth tests discussed here. For the Barton model the relevant previous results for the Neyman alternatives remain true.

Example 2 Revisited

For the Poisson, the appropriate orthonormal polynomials are known as Poisson–Charlier polynomials. We have

$$\pi_r(y) = \sqrt{(\lambda^r/r!)}\sum_{j=0}^{r}(-1)^{r-j}\left({}^rC_j\right)(j!)\left(\lambda^{-j}\right)\left({}^yC_j\right)$$

where $y = 0, 1, 2, \ldots$, from which the orthonormal polynomials to second order are

$$\pi_0(y) = 1 \text{ for all y}, \quad \pi_1(y) = (y/\lambda - 1)\sqrt{\lambda}, \quad \pi_2(y) = \left\{y(y-1)/\lambda^2 - 2y/\lambda + 1\right\}\lambda\sqrt{2}$$

Due to the estimation of λ, $\widehat{V}_1 = 0$. For the data here $\widehat{V}_2 = 2.12$, suggesting a model with greater dispersion than the Poisson. Note that $\widehat{V}_2$ is a standardized version of Fisher's Poisson index of dispersion.

For count data the objective is to test for a multinomial distribution with specified cell probabilities $p_1, \ldots, p_m$. When there are no nuisance parameters this is done by imbedding these probabilities in the smooth alternative cell probabilities

$$\pi_j C(\theta)\exp\left\{\sum_{i=1}^{k}\theta_i h_{ij}\right\}p_j, \quad j = 1, \ldots, m$$

and testing H_0: $\theta = 0$ against K: $\theta \neq 0$. In this formulation the θ_i, $i = 1, \ldots, k$ are real parameters, $\theta = (\theta_1, \ldots, \theta_k)^T$, $C(\theta)$ is a normalizing constant so that $\pi_1 + \ldots + \pi_m = 1$, and the h_{rs} satisfy, for $r, s = 1, \ldots, m$,

$$\sum_{j=1}^{m} h_{rj}h_{sj}p_j = \delta_{rs}, \text{ with } h_{mj} = 1, \quad j = 1, \ldots, m$$

Given cell counts $N_1, \ldots, N_m$, the score test statistic when $k = m - 1$ is Pearson's $X_P^2 = \sum_{j=1}^{m}(N_j - np_j)^2/(np_j)$; more familiarly $X_P^2 = \sum_{i=1}^{m}(O_i - E_i)^2/E_i$.

A generalization of this formulation to allow for nuisance parameters leads to the Pearson–Fisher test when the cell probabilities are estimated by maximum likelihood from the multinomial, and to the Rao and Robson (1974) test when the cell probabilities are estimated by maximum likelihood from the ungrouped data. These are thus identified as smooth tests.

It should be emphasized that using different orthonormal functions in the smooth model results in different tests that detect different alternatives. Which orthonormal functions should be chosen depends on which alternatives one hopes to most powerfully detect. If the hypothesized distribution were uniform, we could choose the Legrendre polynomials, as did Neyman (1937). If it were desirable to test for periodic alternatives we could consider using the series $\{\sin(i\pi x)\sqrt{2}\}$, or the Walsh functions as did Hamdan (1964). The aim is to find an orthonormal series that represents the alternatives of interest in as few terms as possible. Greater power results from doing this. A helpful R package is available at http://www.biomath.ugent.be/~othas/smooth2/Home.html.

Each smooth test for a particular distribution requires an independent study. The small sample distributions of the test statistic and its components should be investigated. Generally the approach to the asymptotic chi-squared distribution is so slow that we recommend finding p-values using the parametric bootstrap. Moreover the powers of the smooth tests should be compared with appropriate competitor tests. In general the most powerful smooth test of fit test is likely to be the sum of the squares of the first few nonzero components; $\widehat{S}_{q+k}$ with $k = 2$, 3, or 4. We recommend augmenting this by the use of the components $\widehat{V}_{q+1}^2, \ldots, \widehat{V}_{q+k}^2$ in an exploratory data analysis fashion. However, in particular cases there are variations to this advice.

Sometimes the data are only available in grouped form. See Best and Rayner (2007) for testing for the grouped exponential and Best et al. (2008) for testing for the grouped normal.

Example 1 Revisited

For the exam mark data in Section 2.1, calculate $y_i = (x_i - \bar{x})/s$. The orthonormal polynomials appropriate for testing normality are often called the Hermite–Chebyshev polynomials. We have

$$\pi_0(y) = 1 \text{ for all } y; \pi_1(y) = y;$$

$$\pi_2(y) = \left(y^2 - 1\right)\Big/\sqrt{2};$$

$$\pi_3(y) = \left(y^3 - 3y\right)\Big/\sqrt{6};$$

$$\pi_4(y) = \left(y^4 - 6y^2 + 3\right)\Big/\sqrt{24};$$

$$\pi_5(y) = \left(y^5 - 10y^3 + 15y\right)\Big/\sqrt{120};$$

and

$$\pi_6(y) = \left(y^6 - 15y^4 + 45y^2 - 15\right)\Big/\sqrt{720}.$$

Given these we calculate, for the above data, $\widehat{V}_1 = \widehat{V}_2 = 0$, due to the estimation of μ and σ, and $\widehat{V}_3 = -0.0361$, $\widehat{V}_4 = -1.4656$, $\widehat{V}_5 = -0.0462$, $\widehat{V}_6 = 1.8907$. Note that $\widehat{V}_3$ and $\widehat{V}_4$ are standardized versions of the usual skewness and kurtosis coefficients. As $\widehat{V}_3, \ldots, \widehat{V}_6$ have asymptotic standard normal distributions, we see that $\widehat{V}_6$ is near significance at the 5% level and that $\widehat{V}_4$ and $\widehat{V}_6$ are much larger than the odd-order moment statistics $\widehat{V}_3$ and $\widehat{V}_5$. These observations suggest an alternative probability model that is symmetric and shorter tailed than the normal. Thus a uniform distribution is a possibility so that we could summarize the data as 'evenly' spread over the range (0, 100) rather than as 48.5 ± 30.7. If the odd-order $\widehat{V}_r$ had dominated the even -order values then a skewed alternative model is suggested, while if both odd and even $\widehat{V}_r$ are large, $|\widehat{V}_r| > 1.65$ say, then a symmetric alternative with longer tails then the normal, such as the Laplace, is indicated.

Modern Developments in Smooth Testing

Are Components Diagnostic?

When testing for a distribution from an exponential family the smooth test statistic is the sum of the squares of specified

components. In particular a single component can be used to test for the distribution. There is a considerable literature in recent years on whether a test based on the rth component may be interpreted as diagnosing the failure or not of the data to be consistent with the rth moment of the specified distribution. Simulation studies demonstrate that for virtually any null distribution component tests are not diagnostic. It is now known that if V_r is significantly large, then any or all of the nonnull moments up to the $2r$th could be the cause.

This issue would all be resolved if, in the score test statistics, the asymptotic covariance matrix was replaced by one that estimated the component variances and covariances consistently, under both the null and alternative hypotheses. Henze and Klar (1996), Henze (1997) and Klar (2000) worked in this vein. Unfortunately the simulation studies in Klar (2000) and Thas et al. (2009) show that convergence of these 'rescaled' components to their asymptotic limits is extremely slow, with samples as large as 10 000 required to achieve satisfactory results. Thus rescaling does not create diagnostic components and inference, for example, to obtain p-values, should involve resampling methods rather than the asymptotic distributions of the statistics involved. Nevertheless, although in the finite samples that occur in practice the rescaled components may be somewhat 'tainted' by higher order moments, it is reasonable to say they are more diagnostic than the raw, unscaled components.

In the power studies we have sighted, powers based on the rescaled components are often less than those based on the unscaled components, and where power gains are achieved it is often at the expense of power loss for alternatives elsewhere in the parameter space.

Our personal preference is to not use rescaled components. When testing for distributions within exponential families, for formal testing we prefer to use $\widehat{V}_{q+1}^2 + \ldots + \widehat{V}_{q+k}^2$ with $k = 2, 3,$ or 4, depending on the hypothesized distribution, and use the individual components in a data analytic fashion, as in Example 1 revisited. The first significant component beyond the qth at best *suggests* that the corresponding moment is the cause of the model failure. Outside of exponential families the situation is a little different.

Generalized Smooth Tests and Cholesky Components

The score test statistic for a smooth model is a quadratic form in the components. If the null hypothesis specifies a distribution from an exponential family of distributions then the score test statistic $\widehat{S}_k$ has the appealing form of being a sum of squares of components that under the null hypothesis are asymptotically independent and asymptotically standard normal. Outside of exponential families this convenient form cannot be expected. This includes when testing for the zero-inflated Poisson, extreme value, negative binomial, generalized Pareto (Rayner et al., 2009: Chapter 11) and gamma (De Boeck et al., 2011). The difficulty for these distributions is that the components are not even asymptotically uncorrelated, so the significance of one component may be associated with the significance of others.

Outside of exponential families an alternative approach is to use the generalized score test. Information about generalized score tests is given, for example, in Rippon and Rayner (2010) and Thas (2010). The generalized smooth tests use the generalized score tests, with the $q \times 1$ nuisance parameter β being estimated by solving $V_r = 0$, for $r = 1, \ldots, q$. The solution, $\tilde{\beta}_0$, is a method of moments estimator. These estimators are not usually fully efficient, and their use often means estimating efficiency is sacrificed to gain interpretable components.

The generalized score test statistic for the Neyman and Barton models is of the form $\tilde{V}^T \tilde{\Sigma}^{-1} \tilde{V}$, where $\tilde{\Sigma}$ is a consistent estimator of the asymptotic covariance matrix of the score $\tilde{V} = (\tilde{V}_{q+1}, \ldots, +\tilde{V}_{q+k})^T$. A *Cholesky decomposition* of $\tilde{\Sigma}^{-1}$ gives $\tilde{\Sigma}^{-1} = MM^T$, where M is upper triangular. Putting $\tilde{V}^* = M^T\tilde{V} = (\tilde{V}^*_{q+1}, \ldots + \tilde{V}^*_{q+k})^T$ gives $\tilde{V}^T\tilde{\Sigma}^{-1}\tilde{V} = \tilde{V}^{*T}\tilde{V}^*$. Thus the generalized score test statistic is of the form $(\tilde{V}^*_{q+1})^2 + \ldots + (\tilde{V}^*_{q+k})^2$. Since for most distributions of interest a multivariate central limit theorem applies and $\tilde{V}^*$ has asymptotic covariance matrix the identity, the elements $\tilde{V}^*_r$ of $\tilde{V}^*$ are asymptotically independent and asymptotically standard normal.

Since M^T is lower triangular, $\tilde{V}^*_r$ is the sum of the first r elements of $\tilde{V}$. It follows that the previous discussion about whether or not the components $\widehat{V}_r$ in the smooth test are diagnostic applies equally to the components $\tilde{V}^*_r$ in the generalized smooth test.

The outcome of this discussion is that when testing for *any* distribution, the generalized score test and Cholesky decomposition together yield components that are equally as convenient as those resulting from the score test when testing for distributions from exponential families. Moreover, because of their construction using the Cholesky decomposition, the data and the model agree in moments up to the qth. If the rth ($r > q$) is first significant Cholesky component, this suggests the data and the model do not agree in moments up to the rth, although the significance may be due to moments up to the $2r$th.

The only caveat on this approach is that the orthonormal polynomial of order r requires the existence of the first $2r$ moments of the null distribution. Thus, for example, using this approach it is not possible to directly test for the Cauchy, which has no moments of any order. One option would be to use the probability integral transformation to essentially test for the continuous uniform distribution on (0, 1). However, the resulting components are then difficult to interpret in terms of the original null hypothesis.

Data-Driven Testing

One of the difficulties associated with the definitions of $g_k^N(x;\theta,\beta)$ and $g_k^B(x;\theta,\beta)$ is the determination of the order k. In finite samples misspecifying the order k can seriously affect the power of the test. If k is chosen to be large, the test will give good protection against a wide range of alternatives. However, the power to detect any particular alternative in the parameter space will decrease as k increases. Conversely, if k is chosen to be small, the test will be quite directional, giving good protection against a small set of alternatives, and none against all others.

The idea behind data-driven smooth tests is to let the data make the decision about the order. See Ledwina (1994), Kallenberg and Ledwina (1995, 1997a,b) and Inglot et al. (1997). The order is chosen to optimize a specified criterion. If L_k is the likelihood of a random sample of size n from

a distribution that is an alternative of order k, it would be natural to maximize L_k by choice of k in some set, say $\{1, 2, \ldots, d\}$, where d is specified before sighting the data. Here d is the maximum order one is prepared to accept. However this procedure would simply choose $k = d$. A penalty term is needed to discourage complexity. The Bayesian information criterion (BIC)

$$\mathrm{BIC}_k = -2 \log L_k + k \log n$$

is appropriate, but the computationally easier modified BIC, $\widehat{S}_k + k \log n$ is often preferred. The optimal order, say K, is taken to be the smallest order that maximizes BIC_k. The test statistic is then chosen to be the score or generalized score statistic involving the first K components. This reduces to the sum of squares of the first K components or Cholesky components, as previously defined. An alternative option is to use Aikaike's information criterion (AIC)

$$\mathrm{AIC}_K = -2\log L_k + 2k$$

or its modified form $\widehat{S}_k + 2k$. BIC penalizes complex models more heavily than AIC. The point is that many different model selection rules are possible. In different circumstances different rules will be appropriate.

Since the order is no longer a predetermined constant but a random variable, the test statistic $\widehat{S}_K$ is no longer asymptotically χ^2 distributed, even when testing for distributions from exponential families. Although asymptotic distribution theory has been developed for some of the data-driven tests, critical values and p-values are best determined using resampling methods.

These data-driven smooth tests have competitive power. Inasmuch as they give protection against misspecifying the order, it would be unreasonable to expect them to have greater power than all smooth tests of specified order. If there is any vagueness in the class of alternatives one hopes to best detect, data-driven smooth tests are an excellent choice.

A more flexible method and one of wider applicability, but one which does not result in omnibus consistent tests, is given in Claeskens and Hjort (2004). They fix the maximal order, and they also consider subset selection. This means that for a given maximal order, say d, the model selection criterion can select any subset of indexes from $\{1, \ldots, d\}$ and the data-driven test statistic is then built from the corresponding components V_j with j in the selected index set.

Model Selection

Suppose now that the order k of a smooth alternative has been determined, and a smooth or generalized smooth test of this order applied. If this test statistic or indeed, any of its components is significant, what can be said about the true model? The moment interpretation of the components may not provide helpful insight. The insignificant θ_r in the order k alternative could be replaced by zero, significant θ_r by their method of moments estimators $\tilde{\theta}_r$, and β by its method of moments estimator under the null hypothesis, $\tilde{\beta}_0$. This approach seems intuitively reasonable, but are there better options?

In Rayner et al. (2009: Chapter 10) two approaches are described: model selection through hypothesis testing and model selection using model selection criteria. Here we focus on the first of these. First suppose $S_h = \{1, 2, \ldots, d\}$ is an index set called the *horizon*. We may use either Neyman or Barton models, but in iterative work it is far more convenient to work with the Barton smooth models

$$g_s^B(x; \theta_s, \beta) = \left\{1 + \sum_{i \in S} \theta_i h_i(x; \beta)\right\} f(x; \beta)$$

in which $S \subset S_h$, $\theta_S = \{\theta_i : i \in S\}$ and $\{h_i(x; \beta)\}$ is a set of functions orthonormal on $f(x; \beta)$. The nonpositivity of $g_S^B(x; \theta_S, \beta)$ is not an issue for score tests. Clearly $g_{S_h}^B(x; \theta_{S_h}, \beta)$ is the most complex model we are prepared to accept. A horizon of four clearly limits the maximal order more than one of 44 does.

We describe model selection through hypothesis testing, which is similar to the familiar forward selection and backward elimination techniques used in regression analysis. In forward selection at the uth step, the model is $g_S^B(x; \theta_S, \beta)$ and we consider whether or not to add a single θ_i term to the model, where $\theta_i \in \theta_{S_u}$, for every possible θ_i not already in the model. A slightly modified score test is derived to test each of these hypotheses. If any are significant at a predetermined level, then the θ_i corresponding to the most significant test is added to the model. Backward elimination is similar, with the least significant θ_i being eliminated from successively reduced models until only significant terms remain in the model. The score test statistics change at each iteration.

It has previously been argued that when a data-driven smooth test rejects the null hypothesis it may be informative to investigate the selected components, even though the diagnostic property may not be guaranteed. Another way forward, however, is to plot the density estimate that corresponds to the selected model. The Barton model is particularly convenient for this purpose. Suppose that $\widehat{S}$ contains the indexes of the selected components, and the appropriate nonparametric density estimate is given by

$$g_{\widehat{S}}^B(x; \tilde{\theta}, \tilde{\beta}_0) = \left\{1 + \sum_{i \in \widehat{S}} \tilde{\theta}_i h_i(x; \tilde{\beta}_0)\right\} f(x; \tilde{\beta}_0)$$

This density estimate is referred to as the *improved density estimate*, but it can only be considered as a genuine density estimate after correcting for the nonpositivity, using the methods proposed in Gajek (1986) and Glad et al. (2003). In Rayner et al. (2009: Chapter 10) we suggest using the plot of the improved density as the basis for the formulation of the conclusions. Since the improved density is merely a graphical representation of the information contained in the data-driven smooth test statistic, the conclusions will be consistent.

Examples and Conclusion

Example 3: Angus Data

Angus (1982) gives 20 operational lifetimes in hours:

6278, 3113, 5236, 11584, 12628, 7725, 8604, 14266, 6125, 9350, 3212, 9003, 3523, 12 888, 9460, 13 431, 17 809, 2812, 11 825, 2398.

In testing the null hypothesis that the data follow the exponential distribution, the Chernoff–Lehmann test with

four classes, the Anderson–Darling, Cramer-von Mises, and Shapiro–Wilk tests give bootstrap p-values 0.01, 0.01, 0.01 and 0.00 respectively. It would appear that the data are not consistent with exponentiality, as Angus (1982) also found. See Figure 1.

We also find $\widehat{S}_4 = \widehat{V}_2^2 + \ldots + \widehat{V}_5^2 = 8.8$ with χ_4^2 p-value is 0.07 and bootstrap p-value based on 1000 bootstrap runs of 0.02. In addition $\widehat{V}_2 = -1.7$, $\widehat{V}_3 = -1.9$, $\widehat{V}_4 = -1.4$, $\widehat{V}_5 = -0.8$. The corresponding asymptotic two-sided p-values are 0.10, 0.06, 0.16, and 0.44, with bootstrap p-values based on 1000 bootstrap runs 0.00, 0.00, 0.04, and 0.22, respectively. Here and elsewhere use of the asymptotic null distribution of the components and the test statistic itself can be misleading. In general it is more desirable to use bootstrap p-values.

The first two components contribute most to $\widehat{S}_4$, suggesting at least dispersion and skewness departures from what would be expected under the exponential model. However, the cause of the significance of the order two components could be due to the third and fourth moments of the true distribution differing from those of the exponential; both corresponding components have p-values less than 5%. Similarly the significance of the order three component could be due to moments of the true distribution up to the sixth, and at this point the order six component has not been assessed.

Now suppose a horizon of $\{2, \ldots, 6\}$ is taken; order one is omitted because the rate is a nuisance parameter and fills the same role as θ_1. In forward selection, at the first step the test statistics corresponding to θ_2 to θ_5 are all significant at the 5% level, but that corresponding to θ_3 is most significant, so that term is included in the model, and this new model assessed. This next assessment finds the term corresponding to θ_4 should be included in the model. A new assessment shows that no further terms are significant, and assessment stops.

In backward elimination the initial model includes θ_2 to θ_6 and successively eliminates first θ_6, then θ_5, then θ_2, and then finds that no further terms warrant removal. Although it need not be the case in general, both forward selection and backward elimination agree here.

Figure 1 shows the hypothesized and the improved density estimates. From this it may be concluded that the true density is probably not a monotonically decreasing density such as the hypothesized exponential density. The improved density suggests that there is a mode close to five and that the distribution is skewed with a tail toward the larger lifetimes.

Statistical model assessment is at the heart of good statistical practice, and is the genesis of modern statistics. In general we suggest using the Anderson–Darling test as an omnibus test. For a more detailed scrutiny of the data, we recommend testing using the smooth or generalized smooth tests with asymptotically uncorrelated components. These tests generally have competitive power and the asymptotically uncorrelated components facilitate exploratory data analysis. In exploratory data analysis, a significant rth component suggests nonzero θ_r and hence the data and the null model differ in moments up to the rth. However with arbitrary alternatives moments up to the $2r$th may be the cause of the model failure. Model selection techniques may be used to construct smooth models consistent with the data. It is more informative and accurate to base exploratory data analysis on these models and their graphical representations than on the

Figure 1 Histogram, density estimates of the hypothesized exponential distribution (dashed line) and the improved density (full line) for the Angus lifetimes data. Lifetimes are given in thousands of hours. The counts in the four classes are 5, 8, 6, and 1.

components themselves. However, these techniques may use many criteria, so there are many possible density plots. Each selected model has implications about which moments may be the cause of model failure, but it is important to remember that this is exploratory data analysis, and perhaps it is the envelope of possible densities that gives insights rather than any particular choice.

Abstract

The problem of statistical identification appears in different guises in many diverse fields. The most interesting form of the problem occurs when a sample of infinite size, assumed to be generated by one member of a class of statistical models indexed by a parameter, does not lead to certain knowledge of one or more elements of that parameter. A different type of identification problem arises when sample size is less than the number of elements of the parameter indexing the class of statistical models assumed to have generated the sample. For example, in the case of ordinary multiple regression, when sample size is less than the number of independent (explanatory) variables, it is not possible to estimate regression coefficients uniquely, even in the absence of collinearity among vectors of independent variable observations. This article focuses on the former type of identification problem and takes a broad view of what is often considered a narrow problem particular to one's given field of interest. Following a brief history of statistical identification, the concept of 'identifiability' is examined and explained from both Bayesian and non-Bayesian viewpoints.

A statistical identification problem arises when a sample of infinite size, assumed to be generated by an element of a class of statistical models indexed by a parameter, does not lead to certain knowledge of one or more components of that parameter. Roughly, a model is identified if enough observed data could allow one to distinguish elements of the parameter set from one another.

Statistical identification problems are ubiquitous, occurring in fields as diverse as reliability, optimal control theory, experimental design, and epidemiology. A rich array of statistical identification problems appear in the social sciences: latent structure analysis, factor analysis, and analysis of covariance structures are based on multivariate statistical models that possess, by construction, this problem. Nonresponse and data censoring in the conduct of sample surveys often lead to an identification problem and the problem is a central feature of the analysis of econometric structural equation models and of errors-in-variables regression models. Experimental designs in which treatments are confounded lead to an identification problem. A nonparametric identification problem occurs in the theory of competing risks.

Understanding if a statistical model is identified, nonidentified, or unidentified is a necessary prelude to the construction of a sensible method for making inferences about model parameters from observed data.

Background

The problem of statistical identifiability appears in economics as early as Pigou (1910). Thurstone discusses identification in his applications of factor analysis to intelligence (1935, 1947) and, in his latent structure analysis of opinion research and attitudes, Lazarsfeld deals with identification issues (1950).

Principal contributions to a rigorous mathematical treatment of the problem began in the 1950s with the work of Haavelmo (1944), Hurwicz (1950), Koopmans et al. (1950), and Koopmans and Reiersøl (1950) and spawned a huge literature on the subject. Fisher (1966) provides a thorough rigorous treatment of identification for simultaneous equation systems. He laid to rest the issue of whether or not identifiability is a discrete or continuous property of parameter estimation by demonstrating that estimators, which are consistent given a correct model specification, converge in probability to true parameter values as specification error approaches zero. Thus, identifiability may be regarded as a continuous property of a set of parameters, and small specification errors lead to small inconsistencies in parameter estimation. Rothenberg (1971) and Bowden (1973) extend identification theory to embrace nonlinear models, distinguishing local from global identifiability. Hannan (1969, 1971) generalizes the theory of identification for linear structural equation systems with serially uncorrelated residual errors in another direction: he establishes conditions for identifiability for the important case of autoregressive moving average error terms (*see* Time Series: General).

Probabilistic models employed in linear system optimal control theory have much in common with econometric structural (simultaneous) equation systems in which observations are measured with random error. In the psychometric literature, the later class of models goes under the acronym LISREL (Linear Structural Relationships). Jöreskog and Sörbom (1984) have developed methods for specifying LISREL model structure, algorithms for calculating various types of parameter estimators, and a framework for interpretation of results. As with econometric structural equation systems, applications of LISREL span a wide domain of social science applications, marketing, psychology, sociology, and organizational behavior among them.

A Bayesian treatment of identification began with Dawid (1979) and Kadane's (1974) studies of identification in Bayesian theory and Drèze's (1972), (1974) analysis of econometric simultaneous equation systems from a Bayesian perspective. Identification through a Bayesian lens is currently

a vigorous area of research yielding new insights into how to construct meaningful prior distributions for parameters.

Example 1

A sample survey is conducted to determine the attitudes of individuals in a population toward a particular subject. The sample frame consists of N individuals, each of whose response is classified as either 'Favorable' or 'Unfavorable.' This sample yields $N_{R\cdot}$ respondents and $N_{S\cdot} = N - N_{R\cdot}$ nonrespondents. Of the $N_{R\cdot}$ respondents, N_{FR} are classified as 'Favorable' and $N_{UR} = N - N_{FR}$ are classified as 'Unfavorable.' In the absence of information bearing directly on the fraction of nonrespondents who would be classified as 'Favorable,' statistics available for inference are N_{FR}, N_{UR}, $N_{S\cdot}$ subject to $N_{FS} + N_{US} = N_{S\cdot}$ and to $N_{FR} + N_{UR} + N_{S\cdot} = N$. Suppose that the process generating data about both respondents and nonrespondents is modeled as a double dichotomy with probabilities p_{FR}, p_{UR}, p_{FS}, and $p_{US} > 0$ and $p_{FR} + p_{UR} + p_{FS} + p_{US} = 1$ as shown in Table 1. Table 2 shows the corresponding tables for the model of observed data.

The probability distribution for observations N_{FR}, N_{UR}, and $N_{S\cdot}$ in Table 1 is proportional to

$$(p_{FS} + p_{US})^{N_{S\cdot}} p_{FR}^{N_{FR}} p_{UR}^{N_{UR}}$$

Observations N_{FR}, N_{UR}, and $N_{S\cdot}$ are sufficient for joint inference about $p_{S\cdot} = p_{FS} + p_{US}$, p_{FS}, and p_{UR}, but even an infinite sample will not lead to knowledge of p_{FS} and p_{US} with certainty: p_{FS} and p_{US} are not identifiable in the presence of nonresponse as an infinite sample yields knowledge only that p_{FS} and p_{US} satisfy $p_{FS} + p_{US} = p_{S\cdot\cdot}$.

Definitions

A statistical 'model' is a family $\{P_\theta, \theta \in \Theta\}$ of probability distributions indexed by a parameter $\theta \in \Theta$. A statistical 'structure' is P_θ for a particular $\theta = \theta_0 \in \Theta$. Parameters θ and $\theta' \in \Theta$ are 'observationally equivalent' if and only if $P_{\theta'}(A) = P_{\theta'}(A)$ for all A in a measurable space $\mathscr{L}$.

Table 1

	Parameters			Observations		
Favorable (F)	p_{FR}	p_{FS}	$p_{F\cdot}$	N_{FR}	N_{FS}	$N_{F\cdot}$
Unfavorable (U)	p_{UR}	p_{US}	$p_{U\cdot}$	N_{UR}	N_{US}	$N_{U\cdot}$
	$p_{R\cdot}$	$p_{S\cdot}$	1.0	$N_{R\cdot}$	$N_{S\cdot}$	N

Table 2

	Parameters		Observations		
Favorable (F)	p_{FR}		N_{FR}		
Unfavorable (U)	p_{UR}		N_{UR}		
	$p_{R\cdot}$	$p_{S\cdot}$	$N_{R\cdot}$	$N_{S\cdot}$	N

Definition: Θ is 'identifiable' if and only if $\theta = \theta'$ for all observationally equivalent pairs $\theta, \theta' \in \Theta$.

In practice, it is useful to couch these definitions in terms of distribution functions: let X be an observable random variable with range $\mathscr{L}_x$ and distribution function $F_\theta(x) \equiv P(X \le x|\theta)$ belonging to a model $\{F_\theta, \theta \in \Theta\}$. If there exists at least one pair (θ, θ') for which $\theta, \theta' \in \Theta$, and $\theta \ne \theta'$ such that $F_\theta(x) = F_{\theta'}(x)$ for all $x \in \mathscr{L}_x$, then we say that Θ is 'nonidentifiable' by X. If Θ is not nonidentifiable by X it is identifiable. These definitions of identifiability can be recast to embrace nonparametric models as well (Basu, 1981; Berman, 1963).

Example 2

In general, unobservables in an 'econometric simultaneous equation model' are restricted to residuals (errors in model equations). A 'factor analysis model,' on the other hand, possesses both unobservable latent and unobservable explanatory variables. Each is a special case of a more general 'structural equation model' in which a 'latent variable model' displaying interactions among latent variables and a 'measurement model' specifying how observable variables are related to latent variables are conjoined. Properties of the covariance matrix of observable variables are at center stage and structural equation test procedures are designed to measure the quality of fit between an observed (sample) covariance matrix Σ and a model based covariance matrix $\Sigma(\theta)$ indexed by a vector θ of model parameters.

Even when the structure of relations between observable variables and latent variables and the structure of relations among latent variables are both linear, the model covariance matrix $\Sigma(\theta)$ may be a complicated, nonlinear function of elements of the parameter vector θ. In this setting, for an element of the parameter vector θ to be identified it must be an explicit, known function of one or more elements of the sample covariance matrix Σ under the hypothesis that $\Sigma = \Sigma(\theta)$. (See Bollen (1989) for a comprehensive treatment and also Hoyle (1995) for applications.) If PDS $\Sigma(\theta)$ is $(k \times k)$, it has at most $\frac{1}{2}k(k+1)$ functionally independent components, so for θ to be identifiable, it can possess at most $\frac{1}{2}k(k+1)$ functionally independent components. This is a generic, easy-to-apply, necessary but not sufficient condition for identifiability of θ.

In the notation of Bollen (1989), we have a latent variable model and a measurement model.

Latent Variable Model

$$\eta = \mathbf{B}^*\eta + \Gamma\xi + \zeta$$

The $(m \times m)$ coefficient matrix $\mathbf{B}^*$ induces interactions among latent endogenous variables $(m \times 1)\eta$, the $(m \times r)$ coefficient matrix Γ establishes the effect of exogenous variables $(r \times 1)\xi$ on η, and $(m \times 1)\zeta$ represents a random residual error term assumed to be uncorrelated with ξ and to possess mean zero and finite (PDS) variance matrix Ψ. In addition $\mathbf{B} \equiv \mathbf{I} - \mathbf{B}^*$ is assumed to be nonsingular.

Measurement Model

$$\mathbf{y} = \mathbf{\Lambda}_y \boldsymbol{\eta} + \boldsymbol{\varepsilon}$$
$$\mathbf{x} = \mathbf{\Lambda}_x \boldsymbol{\xi} + \boldsymbol{\delta}$$

The elements of the $(p \times m)$ coefficient matrix $\mathbf{\Lambda}_y$ determine the magnitude of the effect of levels and changes in levels of latent variables $\boldsymbol{\eta}$ on observable variables $\mathbf{y}$; $(q \times r)\mathbf{\Lambda}_x$ relates exogenous variables $\boldsymbol{\xi}$ to observable variables in $\mathbf{x}$ in a similar fashion. Residual errors $(p \times 1)\boldsymbol{\varepsilon}$ and $(q \times 1)\boldsymbol{\delta}$ are random variables, generally assumed to be uncorrelated with one another, with $\boldsymbol{\eta}$, and with $\boldsymbol{\xi}$ and to possess common mean zero, but possibly different (PDS) covariance matrices $\mathbf{\Theta}_{\varepsilon}$ and $\mathbf{\Theta}_{\delta}$, respectively.

To be specific, focus on the composition of the variance matrix $\mathrm{Var}(\mathbf{y})$ of $\mathbf{y}$ as a function of latent variable model parameters $\mathbf{B}$, $\mathbf{\Gamma}$, $\mathbf{\Phi}$, and $\mathbf{\Psi}$ and measurement model parameters $\mathbf{\Lambda}_y$ and $\mathbf{\Theta}_{\varepsilon}$:

$$\mathrm{Var}(\mathbf{y}) = \mathbf{\Lambda}_y \mathbf{B}^{-1}\left[\mathbf{\Gamma}\mathbf{\Phi}\mathbf{\Gamma}^t + \mathbf{\Psi}\right]\left(\mathbf{B}^{-1}\right)^t \mathbf{\Lambda}_y^t + \mathbf{\Theta}_{\varepsilon}$$

The $(p \times p)$ PDS matrix $\mathrm{Var}(\mathbf{y})$ possesses $\frac{1}{2}p(p+1)$ functionally independent components. The variance matrix $\mathrm{Var}(\boldsymbol{\varepsilon}) = \mathbf{\Theta}_{\varepsilon}$ alone also possesses $\frac{1}{2}p(p+1)$ functionally independent components and, in the absence of restrictions, other than just $\mathbf{\Phi}$ and $\mathbf{\Psi}$ are PDS, $\mathbf{\Lambda}_y$, $\mathbf{B}$, $\mathbf{\Gamma}$, $\mathbf{\Phi}$, and $\mathbf{\Psi}$ possess $\frac{1}{2}m(m+1) + \frac{1}{2}r(r+1) + m(m+p+r)$ additional functionally independent components. As the above equation suggests, it can be a formidable task to verify by direct algebraic analysis whether or not a particular model parameter is, or is not identifiable.

Clearly, parameter matrices $\mathbf{\Lambda}_y$, $\mathbf{B}$, $\mathbf{\Gamma}$, $\mathbf{\Phi}$, and $\mathbf{\Theta}_{\varepsilon}$ cannot be expressed as unique functions of elements of $\mathrm{Var}(\mathbf{y})$ unless restrictions are placed upon them. When one or more components of $\mathbf{B}$ cannot be recovered uniquely as a function of elements of $\mathrm{Var}(\mathbf{y})$, such components are called 'underidentified' or 'nonidentified.' A central task then is to select constraints on latent variable model parameters and measurement model parameters that renders desired parameters 'identifiable.'

If a priori restrictions on parameters of latent variable and measurement model parameters are specified in a way that leads to two or more distinct representations of some components of $\mathbf{B}$ as a function of components of $\mathrm{Var}(\mathbf{y})$, those components of $\mathbf{B}$ are called 'overidentified.' It can happen, of course, that some elements of $\mathbf{B}$ are identified, some are underidentified, and others are overidentified. Bartels (1985) provides an easily accessible treatment of these concepts.

A common form of a priori constraint is to 'specify' that some parameter values are equal to zero. For example, if the modeler assumes that $\mathbf{y}$ and $\mathbf{x}$ are measured without error and that $\mathbf{\Lambda}_y = (m \times m)\mathbf{I}$, $\mathbf{\Lambda}_x = (r \times r)\mathbf{I}$, $\mathrm{Var}(\boldsymbol{\eta}) = \mathrm{Var}(\boldsymbol{\xi}) = \mathbf{\Theta}_{\varepsilon} = \mathbf{\Theta}_{\delta} = 0$ and the variance of $\mathbf{y}$ becomes

$$\mathrm{Var}(\mathbf{y}) = \mathbf{B}^{-1}\left[\mathbf{\Gamma}\mathbf{\Phi}\mathbf{\Gamma}^t + \mathbf{\Psi}\right]\left(\mathbf{B}^{-1}\right)^t.$$

If, in turn, as is often the case in econometric applications, exogenous variables $\mathbf{x}$ are assumed to be predetermined and known with certainty, $\mathbf{\Phi} = \mathbf{0}$. With all these restrictions in force $\boldsymbol{\eta} = \mathbf{y}$, $\boldsymbol{\xi} = \mathbf{x}$, and the latent variable model becomes $\mathbf{By} = \mathbf{\Gamma z} + \boldsymbol{\delta}$. Then, observable $\mathbf{y} = \mathbf{\Pi z} + \mathbf{u}$, with $\mathbf{\Pi} \equiv -\mathbf{B}^{-1}\mathbf{\Gamma}$, $\mathbf{u} = \mathbf{B}^{-1}\boldsymbol{\delta}$, and $\mathrm{Var}(\mathbf{y}) = \mathbf{B}^{-1}\mathbf{\Psi}(\mathbf{B}^{-1})^t \equiv \mathbf{\Omega}$, is called the 'reduced form' of this model.

Provided that predetermined variables $\mathbf{z}$ are uncorrelated with variables $\mathbf{u}$ (weaker assumptions are possible) and that the asymptotic variance matrix of the $\mathbf{z}$'s exists, both $\mathbf{\Pi}$ and $\mathbf{\Omega}$ can be consistently estimated by ordinary least squares. However, the distribution of $\mathbf{y}$, given $\mathbf{z}$, now depends exclusively on parameters $\mathbf{\Pi}$ and $\mathbf{\Omega}$. Premultiplication of both sides of $\mathbf{By} = \mathbf{\Gamma z} + \boldsymbol{\delta}$ by any nonsingular $(m \times m)$ matrix leads to the same reduced form, so all such structures are observationally equivalent and without further restrictions the system is underidentified.

Fisher (1966) provides an elegant and thorough exposition of conditions for identifiability of linear simultaneous equation system model parameters. Among the most important are 'order' and 'rank' conditions established by Koopmans et al. (1950). Suppose interest focuses on a single equation and that exclusion restrictions alone on $\mathbf{y}$ and $\mathbf{z}$ are in force. A (necessary but not sufficient) 'order condition' for parameters of this equation to be identifiable is that the number of variables excluded be greater than or equal to $m - 1$ – one less than the number of components in (endogenous) $\mathbf{y}$. Alternatively, the total number of excluded predetermined variables must be greater than or equal to the number of variables not excluded from this equation, less one (Fisher, 1966: 40–41).

The following argument due to Fisher is a transparent explanation of the origin of the 'rank condition' for linear simultaneous equation systems, first proved by Koopmans et al. (1950). Exclusion of the lth element of the first row $\mathbf{a}_1$ of $m \times (m+r)\mathbf{A} \equiv [\mathbf{B}, \mathbf{\Gamma}]$ is representable as $\mathbf{a}_1\mathbf{c}^{(l)} = 0$, $\mathbf{c}^{(l)}$ an $(m+r) \times 1$ column vector with a one at element l and zeros elsewhere. Thus, k such exclusions of distinct variables may be written in terms of $(m+r) \times k$ $\mathbf{C}$ as $\mathbf{a}_1\mathbf{C} = \mathbf{0}$. Clearly if $\mathbf{a}_1$ is some linear combination of other rows of $\mathbf{A}$, it is not identifiable. Thus, a sufficient condition for $\mathbf{a}_1$ to be identified is that $\mathbf{xAC} = \mathbf{0}$ holds only for $(1 \times m)\mathbf{x}$ of the form $= (\alpha, 0, \ldots, 0)$, α a scalar. In the absence of other a priori restrictions on elements of $\mathbf{a}_1$, this condition is also necessary. When it obtains, the rank of $\mathbf{AC}$ must be $m - 1$. The order condition follows from the observation that the rank of $\mathbf{AC}$ must be less than or equal to that of $\mathbf{C}$, so the number of independent restrictions imposed by $\mathbf{C}$ must be at least $m - 1$.

Estimation

When a linear statistical model is just identified, both consistent and unbiased estimators of its parameters exist. A more general notion of estimability for linear statistical models, first proposed by Bose (1944, 1947), says that a parameter $\boldsymbol{\theta}$ of such a model is (linearly) estimable if there exists a linear function of observations with expectation equal to $\boldsymbol{\theta}$ for each $\boldsymbol{\theta}$ in a prespecified set $\mathbf{\Theta}$. This special case of identifiability, apparently developed independently of the more general theory of identification outlined in this review, has generated a large literature of its own (*see* Factor Analysis and Latent Variable Models in Personality Psychology).

Deistler and Seifert (1978) address the interplay between identification and estimability for a quite general (possibly nonlinear) version of an econometric structural equation model without measurement error. They answer the question "When, for such systems, does identifiability imply existence of consistent estimators?"

Jöreskog (1973) and Wiley (1973) were among the first to specify practical procedures for the estimation of parameters by analysis of the covariance structure of observations generated by a general structural equation model of the form described in Example 2. For a detailed description of parameter estimation via maximum likelihood, instrumental variables, and least squares see, for example, Jöreskog and Sörbom (1984).

Simultaneous Equation Estimates (Exact and Approximate), Distribution of is a crisp summary of methods designed to recover consistent estimates of structural equation parameters, such as Full Information Maximum Likelihood (FIML), Limited Information Maximum Likelihood (LIML), R-class estimators, and two- and three-stage least squares (2 SLS, 3 SLS). A more leisurely presentation of econometric simultaneous equation system identification issues, couched in terms of a two-equation supply and demand model, and the nature of estimation problems they pose, appears in Simultaneous Equation Estimation: Overview.

Bayesian Identification

Non-Bayesians typically assign exact numerical values to a subset of parameters of a statistical model in order to achieve identification of one or more other parameters. Fisher (1961) suggested broadening this special type of a priori specification by replacing exact numerical values with probabilistic constraints. Drèze (1962) took up the challenge in his treatment of Bayesian identification for simultaneous equation estimation models. As before, let $\mathbf{By} + \mathbf{\Gamma z} = \mathbf{u}$ be a 'structural equation system' indexed by matrix parameters consisting of nonsingular $\mathbf{B}$, $\mathbf{\Gamma}$, and PDS $\mathrm{Var}(\mathbf{u}) = \sum$ with reduced form $\mathbf{y} = \mathbf{\Pi z} + \mathbf{v}$, $\mathbf{\Pi} = -\mathbf{B}^{-1}\mathbf{\Gamma}$ and disturbance variance $\mathrm{Var}(\mathbf{v}) = \mathbf{B}^{-1}\sum(\mathbf{B}^{-1})^t \equiv \mathbf{\Omega}$. Because the likelihood function for observations $\mathbf{y}$ can be written as a function of reduced form parameters $\mathbf{\Pi}$ and $\mathbf{\Omega}$ alone, full knowledge of the exact numerical values of elements of $\mathbf{\Pi}$ and $\mathbf{\Omega}$ does not permit recovery of unique values for elements of $\mathbf{B}$, $\mathbf{\Gamma}$, and $\sum$. The map from $\mathbf{\Pi}$ and $\mathbf{\Omega}$ to $\mathbf{B}$, $\mathbf{\Gamma}$, and $\sum$ is one to many. In effect, all nonsingular matrices $\mathbf{B}$ are observationally equivalent and $\mathbf{B}$ is only identifiable in the special case when $f(\mathbf{B}|\mathbf{\Pi}, \mathbf{\Omega})$ is concentrated on a single point in the space of nonsingular matrices $\mathbf{B}$. Nevertheless, one can assign a prior density $g(\mathbf{B}, \mathbf{\Gamma}, \sum)$ to structural parameters, observe data $(\mathbf{Y}, \mathbf{Z})$ and compute a posterior density $f(\mathbf{B}, \mathbf{\Gamma}, \sum|\mathbf{Y}, \mathbf{Z})$ for $\mathbf{B}$, $\mathbf{\Gamma}$, and $\sum$ whether or not the model is identified in a classical sense. Because identifiability is a property of the likelihood function alone, if a proper prior distribution is assigned to a complete set of parameters ($\mathbf{B}$, $\mathbf{\Pi}$, and $\mathbf{\Omega}$ here) the posterior for these parameters is proper whether or not the likelihood function is identified. Such priors must be chosen judiciously: too tight a prior will anchor the posterior on the prior until sample size becomes very large; a very loose proper prior may fail to reflect relevant prior knowledge. To streamline computation of posteriors, Raiffa and Schlaifer (1961) introduced the concept of 'natural conjugate' priors. The functional form of a natural conjugate prior is derived by interpreting parameter as sufficient statistic and vice versa in the likelihood function. A consequence is that both prior and posterior possess the same functional form, a form dictated by the shape of the likelihood function. For simultaneous equation systems, multivariate-, matric- and poly-t posterior distributions for parameters follow and figure prominently in work by Drèze (1976), Drèze and Morales (1976), Drèze and Richard (1983), and Mouchard (1976) (*see* Bayesian Statistics).

To minimize the impact of a priori evidence or, in some cases, to exploit invariance with respect to mapping from one representation of a parameter to another, a diffuse (vague, noninformative) prior can be the prior of choice. However, in some settings, this choice comes at a cost as a diffuse prior may lead to an improper posterior. Lindley and El Sayeed (1968) foreshadow much recent work on the character of diffuse priors. They were perhaps the first to recognize several important features of prior to posterior analysis. First, a proper prior always yields a proper posterior. Second, "…in the functional relationship problem [improper priors] can cause considerable difficulties…" Third, even when the likelihood function is not identifiable, observed data can lead to a posterior that is informative, i.e., different from the prior. Fourth, "uncritical use of improper distributions can lead to inconsistent estimates."

A simple example often used to introduce the idea of nonidentifiability highlights issues raised by diffuse priors.

Example 3

Suppose observations to be independent and identically normal with mean $\boldsymbol{\theta} = \mu_1 + \mu_2$ and variance 1. Then μ_1 and μ_2 are nonidentifiable. Nevertheless, assignment of a proper prior to μ_1 and μ_2 leads to a proper posterior. As the number of observations approaches infinity, the posterior for $\boldsymbol{\theta}$ converges in distribution to a true value $\boldsymbol{\theta}_0$ of $\boldsymbol{\theta}$ and the (proper) posterior for μ_1 and μ_2 concentrates on the line $\boldsymbol{\theta}_0 = \mu_1 + \mu_2$.

If, however, a diffuse prior $d\mu_1$, $-\infty < \mu_1 < \infty$, is assigned to μ_1 and proper prior $g(\boldsymbol{\theta})$ to $\boldsymbol{\theta}$, the posterior for μ_1 remains diffuse irrespective of sample size. Replace the proper prior $g(\boldsymbol{\theta})$ for $\boldsymbol{\theta}$ with a proper prior $h(\mu_2)$ for μ_2. Then, provided the prior for μ_1 is diffuse, the posterior for μ_2 remains the same as the prior $h(\mu_2)$, no matter how many observations are made.

These features of Example 3 suggest that uncritical choice of a diffuse prior can lead to a posterior with unsatisfactory or even unacceptable properties, in particular when the parameter space is of large dimension. For example, Kleibergen and Van Dijk (1997) point out that for simultaneous equation systems "… the order condition reflects overall identification while the rank condition reflects local (non) identification." They show that local nonidentification coupled with a diffuse prior leads to posterior pathology when one attempts Limited Information analysis of a single equation and suggest an

alternative approach. (See Gelfand and Sahu (1999) for other examples.)

Dawid (1979) and Kadane (1974) use conditional independence as a device for a definition of nonidentifiability which embraces both Bayesian and non-Bayesian perspectives. Suppose that an observable X possesses a distribution $F_{\boldsymbol{\theta}}$ determined by a parameter $\boldsymbol{\theta}$ which we partition into two pieces $\boldsymbol{\theta}_1$ and $\boldsymbol{\theta}_2$. If the distribution of $\boldsymbol{X}$ is fully determined by $\boldsymbol{\theta}_1$ alone, $\boldsymbol{\theta} = (\boldsymbol{\theta}_1, \boldsymbol{\theta}_2)$ is nonidentifiable.

When a Bayesian assigns a prior distribution $g(\boldsymbol{\theta})$ to $\boldsymbol{\theta}$, Bayes theorem tells her that the posterior distribution $f(\boldsymbol{\theta}|\mathbf{y})$ for a parameter $\boldsymbol{\theta}$ given data $\mathbf{y}$ is proportional to the product of the likelihood function $\mathbf{L}(\boldsymbol{\theta}|\mathbf{y})$ for $\boldsymbol{\theta}$ given $\mathbf{y}$ and the prior $g(\boldsymbol{\theta})$ assigned to $\boldsymbol{\theta}$. The (posterior) distribution for $\boldsymbol{\theta}_2$ given $\boldsymbol{\theta}_1$ and data $\mathbf{y}$ given prior $g(\boldsymbol{\theta}) = g(\boldsymbol{\theta}_2|\boldsymbol{\theta}_1)h(\boldsymbol{\theta}_1)$ is

$$f(\boldsymbol{\theta}_2|\boldsymbol{\theta}_1,\ \mathbf{y}) \propto \mathbf{L}(\boldsymbol{\theta}_1,\ \boldsymbol{\theta}_2|\mathbf{y})g(\boldsymbol{\theta}_2|\boldsymbol{\theta}_1)h(\boldsymbol{\theta}_1)$$

If $\boldsymbol{\theta}_2$ is absent from the likelihood function,

$$f(\boldsymbol{\theta}_2|\boldsymbol{\theta}_1,\ \mathbf{y}) \propto g(\boldsymbol{\theta}_2|\boldsymbol{\theta}_1)h(\boldsymbol{\theta}_1|\mathbf{y}) \propto g(\boldsymbol{\theta}_2|\boldsymbol{\theta}_1)$$

so that while data will modify her prior judgements about $\boldsymbol{\theta}_1$, no amount of observable data $\mathbf{y}$ will change her a priori probability assessment $g(\boldsymbol{\theta}_2|\boldsymbol{\theta}_1)$ for $\boldsymbol{\theta}_2$ given $\boldsymbol{\theta}_1$. Data $\mathbf{y}$ is, however, unconditionally informative about $\boldsymbol{\theta}_2$; as data accrues and we learn more about $\boldsymbol{\theta}_1$, prior judgements about $\boldsymbol{\theta}_2$ are modified in accord with

$$f(\boldsymbol{\theta}_2|\mathbf{y}) \propto \int g(\boldsymbol{\theta}_2|\boldsymbol{\theta}_1)h(\boldsymbol{\theta}_1|\mathbf{y})\mathrm{d}\boldsymbol{\theta}_1$$

provided that both $g(\boldsymbol{\theta}_2|\boldsymbol{\theta}_1)$ and $h(\boldsymbol{\theta}_1|\mathbf{y})$ are proper distributions.

Return to Example 1. As Bayesians, (noting that $p_{\mathrm{FR}} + p_{\mathrm{UR}} + p_{\mathrm{FS}} + p_{\mathrm{US}} = 1$), we assign a prior distribution $g(p_{\mathrm{FR}}, p_{\mathrm{UR}}, p_{\mathrm{FS}})$ to $p_{\mathrm{FR}}, p_{\mathrm{UR}}, p_{\mathrm{FS}}$. If observed data $\mathbf{y} = (N_{\mathrm{S}\cdot}, N_{\mathrm{FR}}, N_{\mathrm{UR}})$ is generated in accord with Table 2, the likelihood function for $p_{\mathrm{FR}}, p_{\mathrm{UR}}, p_{\mathrm{FS}}$,

$$[1 - p_{\mathrm{FR}} - p_{\mathrm{UR}}]^{N_{\mathrm{S}\cdot}} p_{\mathrm{FR}}^{N_{\mathrm{FR}}} p_{\mathrm{UR}}^{N_{\mathrm{UR}}}$$

does not depend on $p_{\mathrm{FS}\cdot}$ Consequently,

$$f(p_{\mathrm{FS}}|p_{\mathrm{FR}}, p_{\mathrm{UR}}, \mathbf{y}) \propto g(p_{\mathrm{FS}}|p_{\mathrm{FR}}, p_{\mathrm{UR}})$$

This matches our intuition: given $p_{\mathrm{FR}} + p_{\mathrm{UR}} = \alpha$ we then know with certainty that $p_{\mathrm{FS}} + p_{\mathrm{US}} = 1-\alpha$, $p_{\mathrm{FS}}, p_{\mathrm{US}} \geq 0$. Data of type $(N_{\mathrm{S}\cdot}, N_{\mathrm{FR}}, N_{\mathrm{UR}})$ refines our knowledge about the value of α, but even an infinite sample of this type will not lead to knowledge certain of $p_{\mathrm{FS}\cdot}$ The conditional distribution of p_{FS} given $p_{\mathrm{FR}} + p_{\mathrm{UR}} = \alpha$ prior to observing $\mathbf{y}$ is the same as the conditional distribution of p_{FS} given $p_{\mathrm{FR}} + p_{\mathrm{UR}} = \alpha$ posterior to observing $\mathbf{y}$.

While the theory of identification in a classical statistical context is now well understood, the story of identification from a Bayesian viewpoint is still unfolding. Markov Chain Monte Carlo (MCMC) methods breathe new life into Bayesian inference, allowing efficient computation of normalizing constants and parameter estimates for complex models. An explosion of Bayesian application of MCMC methods surfaces new identification issues. In their study of Bayesian identifiability for 'Generalized Linear Models' (GLMs), Gelfand and Sahu (1999) present conditions under which assignment of an improper prior distribution to some components of a parameter set leads to a proper posterior distribution. More particularly, if a posterior distribution for parameters is improper, under what conditions do there exist a lower-dimensional parameter set that possesses a proper posterior distribution? Ghosh et al. (2000) prove that when data $\mathbf{y}$ is uninformative about $\boldsymbol{\theta}_2$ given $\boldsymbol{\theta}_1$ so that $\boldsymbol{\theta}_2$ is not identifiable, the posterior density $f(\boldsymbol{\theta}_2, \boldsymbol{\theta}_1|\mathbf{y})$ is proper if and only if both $h(\boldsymbol{\theta}_1|\mathbf{y})$ and $g(\boldsymbol{\theta}_2|\boldsymbol{\theta}_1)$ are proper; a fact that Gelfand and Sahu use to establish that for GLMs, at least, even when the posterior distribution for all parameters is improper, there are embedded lower dimensional models that possess a proper posterior distribution, although, in general, that distribution is not uniquely determined. (See Gelfand and Sahu (1999) for conditions that guarantee uniqueness.) They warn, however, that model fitting using MCMC methods is "…somewhat of an art form, requiring suitable trickery and turning to obtain results in which we can have confidence."

Statistical Pattern Recognition

Richard M Golden, University of Texas at Dallas, Richardson, TX, USA

© 2015 Elsevier Ltd. All rights reserved.

Abstract

Statistical pattern recognition is concerned with the problem of designing machines that can detect and classify complex patterns in data. Statistical pattern recognition problems frequently arise in all fields of science and engineering. In particular, statistical pattern recognition methods are widely used by social and behavioral scientists in data analysis and in the course of modeling complex social, behavioral, and neural systems. This article reviews the major components of statistical pattern recognition systems and discusses methods for classification and learning. In addition, the importance of evaluating generalization performance using cross-validation measures and other out-of-sample measures is emphasized.

Statistical pattern recognition is concerned with the problem of using statistical techniques to design machines that can detect and classify patterns of measurement data in useful ways. Such techniques are successfully applied in areas such as object recognition, speech recognition, fingerprint recognition, data analysis, document classification, image analysis, information retrieval, bioinformatics, signal processing, cognitive modeling, machine learning, and artificial intelligence. Examples of statistical pattern recognition machines include many popular connectionist and computational neuroscience models (Golden, 1996). After identifying key 'features' of information in the measurement data, a statistical pattern recognition machine uses its expectations about the 'likelihood' of those features and the 'losses' of making situation-specific decisions to select a classification action that minimizes an appropriate expected risk function. In many cases, the statistical pattern recognition machine must 'learn' through experience the relative likelihood of occurrence of patterns of features in its environment. Although typically viewed as a branch of artificial intelligence or engineering science, statistical pattern recognition methods have been extensively and successfully applied to many behavioral modeling and data analysis problems.

Generic Statistical Pattern Recognition Machine

As shown in Figure 1, a generic statistical pattern recognition machine may be described in terms of four major components: (1) feature extraction, (2) knowledge representation of both loss and probabilistic uncertainty, (3) a Bayes decision rule for classification, and (4) an optional mechanism for learning.

Feature Selection and Extraction

The pattern of measurement data to be classified is represented as a measurement vector (i.e., a point in 'measurement space'). The choice of the measurement space is primarily determined by problem-imposed considerations such as the types of available transducers and the types of patterns that must be processed. The particular pattern classification methodology embodied in the pattern recognition machine usually has little or no influence over the choice of the measurement space. Each measurement vector is then mapped into a feature vector (i.e., a 'point' in feature space) whose dimensions are primarily chosen to facilitate pattern classification by the pattern recognition machine. This (possibly nonlinear) transformation is a crucial component of the researcher's design of the statistical pattern recognition machine (Duda et al., 2001; Hastie et al., 2009). The design of the measurement space to feature space transformation may be informed by prior knowledge (Duda et al., 2001; Hastie et al., 2009; Nilsson, 1965), optimally chosen using appropriate statistical tests (see Golden, 2003; for an example of such a test), or learned using support vector machine or multilayer artificial neural network learning methods such as backpropagation (Duda et al., 2001; Golden, 1996; Hastie et al., 2009; Nilsson, 1965). The process that maps a measurement vector $\mathbf{s}$ into a d-dimensional feature vector $\mathbf{x}$ is called the feature selection and extraction stage of the pattern recognition process.

For example, Figure 1 shows a digital image of a dog represented by a matrix of image pixels. The matrix has 227 rows and 304 columns of image pixels. Each image pixel, in turn, is represented by a positive integer ranging in value from 1 to 256 indicating the image intensity of that pixel. Thus, the measurement vector in this example is a real vector consisting of $227 \times 304 = 69\,008$ elements.

The feature space in this example is generated by the feature selection and extraction stage that transforms a 69 008-dimensional measurement vector into a 7-dimensional feature vector by an appropriate feature map. Useful feature maps for this type of problem include spatial Fourier transforms, spatial derivative transformations, support vector machines, kernel methods, or multilayer feedforward artificial neural network preprocessing transformations. Such approaches as well as others are discussed by Duda and Hart (1973), Duda et al. (2001), and Hastie et al. (2009).

Probabilistic Knowledge Representation

Knowledge is implicitly represented in a statistical pattern recognition machine in several ways. The particular process for mapping points in measurement space into feature space discussed in the previous section is one important knowledge source. However, the expected likelihood of observing a particular feature vector and the associated losses for making different situation-specific decisions are also critical knowledge sources.

Specifically, let the symbol ω_j denote the jth pattern class in a set of J possible pattern classes (i.e., $j = 1, \ldots, J$). Thus, ω_1 refers to the first pattern class (e.g., a set of photographs of

Figure 1 Flow chart of a generic statistical pattern recognition machine. In this example, the sensor array (represented as a measurement vector) detects a pattern of light intensities produced from light reflecting off the head of a dog. A feature selection and extraction stage transforms the measurement vector into a feature vector. Using the feature vector and its probabilistic knowledge representation and loss function representation of the consequences of its decision actions, the pattern recognition machine selects the minimum expected risk decision (i.e., 'Decide Dog').

'dogs') that might have generated the observed feature vector $\mathbf{x}$, while the symbol ω_2 refers to a second competing pattern class (e.g., a set of photographs of 'cats') that might have generated $\mathbf{x}$. The likelihood of observing a feature vector $\mathbf{x}$ corresponding to a particular pattern class is expressed in terms of two types of probability densities. The a priori class probability density $p(\omega_j)$ indicates the likelihood that a feature vector is generated from pattern class ω_j when information about the feature vector $\mathbf{x}$ is not available. The class conditional probability density $p(\mathbf{x}|\omega_j)$ indicates the conditional likelihood of observing the feature vector $\mathbf{x}$ given knowledge that the feature vector $\mathbf{x}$ was generated from pattern class ω_j.

Knowledge regarding the expected consequences of taking a particular classification action α_k given that the feature vector came from pattern class ω_j is also required. Assume there are K possible actions so that $k = 1, \ldots, K$. Typically, the classification action takes the form of a decision indicating which of a finite number of pattern classes generated the feature vector. Formally, it is assumed that a loss $\lambda(\alpha_k|\omega_j)$ is incurred when classification action α_k is taken given that the feature vector was in fact generated from pattern class ω_j.

Referring to the example in Figure 1 assumes two pattern classes $\omega_1 =$ 'Dog' and $\omega_2 =$ 'Cat' and three possible actions: $\alpha_1 =$ 'Decide Dog,' $\alpha_2 =$ 'Decide Cat,' and $\alpha_3 =$ 'Decide Uninterpretable.'

Finally, although assumptions of a finite number of classes and actions are commonly made in the literature, one might extend the traditional statistical pattern recognition framework to include situations involving infinite numbers of pattern classes or infinite numbers of possible classification actions. In such situations, an 'action' is a real vector whose values are estimated (e.g., the amount of pressure to be applied to an accelerator or brake pedal of a car).

Bayes Decision Rule for Classification

The optimal decision rule for selecting a classification action α^* generated by pattern class ω_j is to select α^* such that $\lambda(\alpha^*|\omega_j) \geq \lambda(\alpha_k|\omega_j)$ for $k = 1, \ldots, K$. In practice, however, the pattern class ω_j that actually generated the feature vector is unobservable. The statistical pattern recognition machine does, however, have knowledge of (1) the observed feature vector $\mathbf{x}$, (2) a representation of environmental uncertainty (i.e., the probability density $p(\mathbf{x}|\omega_j)$ and probability mass function $p(\omega_j)$), and (3) a representation of the consequences of the machine's actions (i.e., the loss function $\lambda(\alpha_k|\omega_j)$).

One possible rational inductive decision-making strategy is called the Bayes decision rule for classification; it forms the basis for classification decisions in most statistical pattern recognition algorithms. Bayes decision rules can be derived from classical axioms of rational decision making (see Golden, 1996; for a review). The Bayes decision rule for classification dictates that the pattern recognition machine should select the classification action α^* that minimizes the expected loss or conditional risk given feature vector $\mathbf{x}$ is observed. Formally, the conditional Bayes risk function for classification $R(\alpha_k|\mathbf{x})$ is defined by the formula

$$R(\alpha_k|\mathbf{x}) = \sum_{j=1}^{J} \lambda(\alpha_k|\omega_j) p(\omega_j|\mathbf{x}) \qquad [1]$$

The important minimum probability of error case of eqn [1] arises when $\lambda(\alpha_k|\omega_j) = 1$ when $j \neq k$ and $\lambda(\alpha_k|\omega_j) = 0$ when $j = k$. In this '0–1 loss function case', eqn [1] becomes

$$R(\alpha_k|\mathbf{x}) = \sum_{j \neq k, j=1}^{J} p(\omega_j|\mathbf{x}) = 1 - p(\omega_k|\mathbf{x}) \qquad [2]$$

The action α^* that minimizes the probability of error case eqn [2] of the conditional risk function eqn [1] is usually called a maximum a posteriori (MAP) estimate since α_k maximizes the a posteriori density $p(\omega_k|\mathbf{x})$ (i.e., the likelihood of pattern class ω_k after observing the feature vector $\mathbf{x}$).

Thus, a minimum probability of error decision for the example in Figure 1 is implemented by penalizing the machine with a loss of one when the statistical pattern recognition machine does not decide 'cat' when a photograph of a cat is presented and does not decide 'dog' when a photograph of a dog is presented. All other decisions by the machine are penalized with a loss value of zero.

Now note that the risk $R(\alpha_k|\mathbf{x})$ in eqn [1] can be expressed in terms of the a priori class likelihoods and class conditional likelihoods using the formula $p(\omega_j|\mathbf{x}) = p(\mathbf{x}|\omega_j)p(\omega_j)/p(\mathbf{x})$. Substituting this expression into eqn [1], it follows that the risk, $R(\alpha_k|\mathbf{x})$, for selecting action α given feature vector $\mathbf{x}$ is observed can be expressed as

$$R(\alpha_k|\mathbf{x}) = \left(\frac{1}{p(\mathbf{x})}\right)\sum_{j=1}^{J}\lambda(\alpha_k|\omega_j)p(\mathbf{x}|\omega_j)p(\omega_j) \qquad [3]$$

In practice, direct computation of eqn [3] may be computationally intractable, and so for computational reasons, some monotonically decreasing function of $R(\alpha_k|\mathbf{x})$ is usually defined as a discriminant function $\phi_k(\mathbf{x})$ (e.g., Duda et al., 2001; Hastie et al., 2001). For example, a useful discriminant function for eqn [3] that does not require computing $p(\mathbf{x})$ is given by the formula $\phi_k(\mathbf{x}) = \sum_{j=1}^{J}\lambda(\alpha_k|\omega_j)p(\mathbf{x}|\omega_j)p(\omega_j)$.

Such discriminant functions define 'decision boundaries' in feature space. For example, suppose that there are only two actions α_1 and α_2 corresponding, respectively, to selecting pattern classes ω_1 and ω_2. To implement a decision rule that minimizes the expected risk, the feature vector $\mathbf{x}$ is classified as a member of pattern class ω_1 if $\phi_1(\mathbf{x}) < \phi_2(\mathbf{x})$ and the feature vector $\mathbf{x}$ is classified as a member of pattern class ω_2 if $\phi_1(\mathbf{x}) > \phi_2(\mathbf{x})$. The 'decision boundary' between the pattern classes ω_1 and ω_2 in feature space is defined by the set of points $\{\mathbf{x} : \phi_1(\mathbf{x}) = \phi_2(\mathbf{x})\}$.

Learning

Knowledge Representations

The generic strategy for classification outlined in the previous selection requires knowledge of the (1) a priori class probabilities $p(\omega_1), \ldots, p(\omega_J)$, (2) class conditional likelihoods/densities $p(\mathbf{x}|\omega_1), \ldots, p(\mathbf{x}|\omega_J)$, and (3) loss function $\lambda(\alpha_k|\omega_j)$ associated with selecting classification action α_k given the correct classification of the feature vector is class ω_j. Typically, it is assumed that the a priori class probabilities $p(\omega_1), \ldots, p(\omega_J)$ either are known or can be reliably estimated from previous data. It is also typically assumed that the incurred loss function $\lambda(\alpha_k|\omega_j)$ is always explicitly known.

Thus, the objective of the learning problem is to identify the class conditional likelihoods. A typical strategy for approaching this problem is to define a class conditional probability model for pattern class ω_j that consists of a collection of alternative choices of class conditional likelihoods for pattern class ω_j where each element, $p(\mathbf{x}|\boldsymbol{\beta}, \omega_j)$, of the class conditional probability model is a probability density uniquely identified by a particular value of the q-dimensional parameter vector $\boldsymbol{\beta} \in \mathscr{R}^q$. Note that these modeling assumptions imply the training vectors generated from a particular pattern class ω_k for a particular parameter value $\boldsymbol{\beta}^*$ are a realization of a sequence of independent and identically distributed (i.i.d.) random vectors. The a priori preference for a particular element $p(\mathbf{x}|\boldsymbol{\beta}_j, \omega_j)$ in the class conditional probability model is given by the a priori parameter density $p(\boldsymbol{\beta})$. Given $p(\mathbf{x}|\boldsymbol{\beta}, \omega_j)$, $p(\boldsymbol{\beta})$, and the training data $\mathscr{D}_n$ the objective of the learning problem is to identify the class conditional density $p(\mathbf{x}|\omega_j)$ through the examination of the elements of the class conditional probability model $\{p(\mathbf{x}|\boldsymbol{\beta}, \omega_j) : \boldsymbol{\beta} \in \mathscr{R}^q\}$.

Environmental Modeling Assumptions

We assume that $(\mathbf{x}^i, \omega^i)$, $i = 1, \ldots, n$ is a realization of a sequence of i.i.d. random vectors $(\mathbf{X}^i, \boldsymbol{\omega}^i)$, $i = 1, \ldots, n$ where the notation $(\mathbf{x}^i, \omega^i)$ indicates that the ith pattern vector originated from pattern class $\omega^i \in \{\omega_1, \ldots, \omega_J\}$. We assume $\mathbf{x}^i$ takes on a countable number of possible values in a set $\Omega \subseteq \mathscr{R}^d$. However, we do not necessarily assume that $(\mathbf{X}^i, \boldsymbol{\omega}^i)$ is completely observable. Rather we assume that the training data $\mathscr{D}_n$ is defined as a collection of n data observable vectors $\mathbf{y}^1, \ldots, \mathbf{y}^n$ that are realizations of a completely observable stochastic process of (conditionally) i.i.d. random vectors $\mathbf{Y}^1, \ldots, \mathbf{Y}^n$ with common density $p(\mathbf{y}^i|\mathbf{x}^i, \boldsymbol{\omega}^i)$. The marginal density $p(\mathbf{y}^i|\boldsymbol{\beta}) \equiv \sum_{j=1}^{J}\sum_{\mathbf{x}\in\Omega} p(\mathbf{y}^i|\mathbf{x}, \omega_j)p(\mathbf{x}|\boldsymbol{\beta}, \omega_j)p(\omega_j)$ is used to model the observable component of the data in terms of the class conditional densities and a priori class probabilities. The assumption that $(\mathbf{X}^i, \boldsymbol{\omega}^i)$ and $\mathbf{Y}^1, \ldots, \mathbf{Y}^n$ are i.i.d. discrete random vectors can be considerably relaxed and is made only for expository reasons.

Supervised, Unsupervised, and Reinforcement Learning Paradigms

For the case of supervised learning, the observable training data has the property that $p(\mathbf{Y}^i = [\mathbf{x}^i, \omega^i]|\mathbf{x}^i, \omega^i) = 1$ if the pattern $\mathbf{x}^i$ and the pattern class ω^i from which $\mathbf{x}^i$ originated are both completely observable. Thus,

$$p(\mathbf{y}^i|\boldsymbol{\beta}) \equiv \sum_{j=1}^{J}\sum_{\mathbf{x}\in\Omega} p(\mathbf{y}^i|\mathbf{x}, \omega_j)p(\mathbf{x}|\boldsymbol{\beta}, \omega_j)p(\omega_j) = p(\mathbf{x}^i, \omega^i|\boldsymbol{\beta})$$

For the case of unsupervised learning, the observable training data has the property that $p(\mathbf{Y}^i = \mathbf{x}^i|\mathbf{x}^i, \omega^i) = 1$ corresponding to the case where every pattern $\mathbf{x}^i$ is completely observable yet the pattern class ω^i from which $\mathbf{x}^i$ originated is not observable. Thus,

$$\begin{aligned} p(\mathbf{y}^i|\boldsymbol{\beta}) &\equiv \sum_{j=1}^{J}\sum_{\mathbf{x}\in\Omega} p(\mathbf{y}^i|\mathbf{x}, \omega_j)p(\mathbf{x}|\boldsymbol{\beta}, \omega_j)p(\omega_j) \\ &= \sum_{j=1}^{J} p(\mathbf{x}^i|\boldsymbol{\beta}, \omega_j)p(\omega_j) = p(\mathbf{x}^i|\boldsymbol{\beta}) \end{aligned}$$

Note that the unsupervised learning case is formally equivalent to a 'clustering analysis' problem where the training data originates from different clusters $\omega_1, \ldots, \omega_J$ yet the identity of the cluster for a given pattern vector is not observable.

For the case of reinforcement learning, one receives only a 'hint' regarding the identity of the pattern $\mathbf{x}^i$ and pattern class ω^i through observing $\mathbf{y}^i$. That is, the identity of the pattern $\mathbf{x}^i$

and pattern class ω^i are only partially observable. For example, $\mathbf{y}^i$ might be a scalar-valued variable that reveals only a subtle clue regarding the identity of pattern $\mathbf{x}^i$ and the pattern class ω^i from which $\mathbf{x}^i$ originated.

Estimative Approach: A Bayes Risk Function for Learning

A Bayes risk function estimative approach (Aitchison, 1975; Patrick, 1972) may be defined as finding $\hat{\boldsymbol{\beta}}$ that minimizes the conditional Bayes risk function for learning: $R(\boldsymbol{\beta}|\mathscr{D}_n) \equiv \int c(\boldsymbol{\beta}, \ddot{\boldsymbol{\beta}}) p(\ddot{\boldsymbol{\beta}}|\mathscr{D}_n) d\ddot{\boldsymbol{\beta}}$ where $c(\hat{\boldsymbol{\beta}}, \ddot{\boldsymbol{\beta}})$ denotes the loss incurred in taking the action of 'plugging in' the constant $\hat{\boldsymbol{\beta}}$ into the class conditional model formula $p(\mathbf{x}|\hat{\boldsymbol{\beta}}, \omega_j)$ to obtain the class conditional density $p(\mathbf{x}|\omega_j) \equiv p(\mathbf{x}|\hat{\boldsymbol{\beta}}, \omega_j)$ when the data was, in fact, generated from the class conditional density $p(\mathbf{x}|\ddot{\boldsymbol{\beta}}, \omega_j)$. This methodology is analogous to minimizing expected risk during pattern classification as described in Section Generic statistical pattern recognition machine. The a posteriori density $p(\ddot{\boldsymbol{\beta}}|\mathscr{D}_n)$ is calculated using the formula $p(\ddot{\boldsymbol{\beta}}|\mathscr{D}_n) = p(\mathscr{D}_n|\ddot{\boldsymbol{\beta}}) p(\ddot{\boldsymbol{\beta}}) / p(\mathscr{D}_n)$ where $p(\mathscr{D}_n|\ddot{\boldsymbol{\beta}})$ is called the likelihood function because it specifies the likelihood of the observed data given the parameter vector $\ddot{\boldsymbol{\beta}}$.

For expository reasons, assume that $p(\ddot{\boldsymbol{\beta}}|\mathscr{D}_n)$ is a probability mass function so that $\ddot{\boldsymbol{\beta}}$ takes on only a finite number of values. We now consider the important '0–1 loss function special case' where $c(\hat{\boldsymbol{\beta}}, \ddot{\boldsymbol{\beta}}) = 1$ if $\hat{\boldsymbol{\beta}} \neq \ddot{\boldsymbol{\beta}}$ and $c(\hat{\boldsymbol{\beta}}, \ddot{\boldsymbol{\beta}}) = 0$ only if $\hat{\boldsymbol{\beta}}_j = \ddot{\boldsymbol{\beta}}_j$ (i.e., it is assumed that there is a uniquely correct choice for the parameter values). Furthermore, to simplify the exposition, we also temporarily assume that $p(\ddot{\boldsymbol{\beta}}|\mathscr{D}_n)$ is a probability mass function so that $\ddot{\boldsymbol{\beta}}$ takes on only a finite number of values (e.g., $\ddot{\boldsymbol{\beta}}$ is 'quantized'). Then we have $R(\boldsymbol{\beta}|\mathscr{D}_n) \equiv \sum_{\ddot{\boldsymbol{\beta}} \in \Omega} c(\boldsymbol{\beta}, \ddot{\boldsymbol{\beta}}) p(\ddot{\boldsymbol{\beta}}|\mathscr{D}_n) = 1 - p(\boldsymbol{\beta}|\mathscr{D}_n)$. Thus, the 0–1 loss function special case corresponds to a minimum probability decision rule of selecting a 'most probable' value of the quantized $\ddot{\boldsymbol{\beta}}$ given the observed data $\mathscr{D}_n$. Because this learning strategy involves maximizing the a posteriori density $p(\boldsymbol{\beta}|\mathscr{D}_n)$, it is referred to as a MAP estimation learning strategy. A global maximizer $\tilde{\boldsymbol{\beta}}$ of the a posteriori density $p(\boldsymbol{\beta}|\mathscr{D}_n)$ is called a MAP estimate. Since $\mathbf{Y}_1, \ldots, \mathbf{Y}_n$ are i.i.d., the negative normalized log-likelihood $l_n(\boldsymbol{\beta}) \equiv -\frac{1}{n} \log p(\mathscr{D}_n|\boldsymbol{\beta})$ where $-\frac{1}{n} \log p(\mathscr{D}_n|\boldsymbol{\beta}) = -\frac{1}{n} \sum_{i=1}^{n} \log p(\mathbf{y}^i|\boldsymbol{\beta})$. A global minimizer $\hat{\boldsymbol{\beta}}_n$ of the negative normalized likelihood is called a maximum likelihood (ML) estimate.

The negative normalized log-likelihood $l_n(\boldsymbol{\beta})$ measures the likelihood of the observed data for a given parameter value in contrast to $p(\boldsymbol{\beta}|\mathscr{D}_n)$, which is the likelihood of a parameter value given the observed data. As $n \to \infty$, $l_n(\boldsymbol{\beta})$ converges to the cross-entropy $l(\boldsymbol{\beta}) \equiv -\sum_{\mathbf{y}} p(\mathbf{y}) \log p(\mathbf{y}|\boldsymbol{\beta})$ between the observable data distribution and the researcher's model of the observable data distribution.

Using the relation $p(\mathscr{D}_n|\boldsymbol{\beta}) = \exp[-n l_n(\boldsymbol{\beta})]$, an explicit formula for $p(\boldsymbol{\beta}|\mathscr{D}_n)$ is given by

$$p(\boldsymbol{\beta}|\mathscr{D}_n) = \exp[-n(l_n(\boldsymbol{\beta}) - \frac{1}{n} \log p(\boldsymbol{\beta}) + \frac{1}{n} \log p(\mathscr{D}_n))] \quad [4]$$

where inspection of eqn [4] shows that for large sample size n, a global minimizer of $l_n(\boldsymbol{\beta})$ (i.e., an ML estimate) will be an approximate global maximizer of $p(\boldsymbol{\beta}|\mathscr{D}_n)$ (i.e., a MAP estimate) because $\frac{1}{n} \log p(\mathscr{D}_n)$ is a constant on the parameter space and $\frac{1}{n} \log p(\boldsymbol{\beta}) \to 0$ (under typically assumed conditions).

Predictive Approach: Bayesian Learning

The key idea of the estimative approach in Section Estimative approach: a Bayes risk function for learning was that the class conditional density $p(\mathbf{x}|\omega_j)$ is obtained by 'plugging in' a particular parameter value $\hat{\boldsymbol{\beta}}$ (that minimizes a Bayes risk function) into the class conditional model formula $p(\mathbf{x}|\boldsymbol{\beta}, \omega_j)$ to obtain $p(\mathbf{x}|\omega_j) = p(\mathbf{x}|\boldsymbol{\beta}, \omega_j)$. An alternative Bayesian approach referred to as the 'predictive approach' by Aitchison (1975) is to integrate $p(\mathbf{x}|\boldsymbol{\beta}, \omega_j)$ using the formula

$$p(\mathbf{x}|\omega_j) = \int p(\mathbf{x}|\boldsymbol{\beta}, \omega_j) p(\boldsymbol{\beta}|\mathscr{D}_n) d\boldsymbol{\beta} \quad [5]$$

Aitchison (1975) provides a theoretical analysis demonstrating that for a wide range of situations the predictive approach is superior to the estimative approach based upon a cross-entropy goodness-of-fit criterion. However, the practical difficulty of applying the predictive approach is that the integral in eqn [5] is typically computationally intractable. In this section, we will discuss analytic and simulation methods for evaluating the integral in eqn [5].

Analytic Methods for Applying the Predictive Approach

In this section, we informally discuss an analytic formula for approximating the integral in eqn [5] valid for sufficiently large sample sizes (Tierney and Kadane, 1986). The integral in eqn [5] may be rewritten as

$$\begin{aligned} p(\mathbf{x}|\omega_j) &= \int p(\mathbf{x}|\boldsymbol{\beta}, \omega_j) \left(\frac{p(\mathscr{D}_n|\boldsymbol{\beta}) p(\boldsymbol{\beta})}{p(\mathscr{D}_n)} \right) d\boldsymbol{\beta} \\ &= \frac{\int p(\mathbf{x}|\boldsymbol{\beta}, \omega_j) p(\mathscr{D}_n|\boldsymbol{\beta}) p(\boldsymbol{\beta}) d\boldsymbol{\beta}}{\int p(\mathscr{D}_n|\boldsymbol{\beta}) p(\boldsymbol{\beta}) d\boldsymbol{\beta}} \end{aligned}$$

Now let $\psi_j(\boldsymbol{\beta}) = -n^{-1} \log(p(\mathbf{x}|\boldsymbol{\beta}, \omega_j) p(\mathscr{D}_n|\boldsymbol{\beta}) p(\boldsymbol{\beta}))$ and $\overline{\psi}(\boldsymbol{\beta}) = -n^{-1} \log(p(\mathscr{D}_n|\boldsymbol{\beta}) p(\boldsymbol{\beta}))$. Let $\hat{\boldsymbol{\beta}}_j$ and $\overline{\boldsymbol{\beta}}$ be the respective global minimizers of ψ_j and $\overline{\psi}$. Let the notation $\mathscr{I}^j(\psi_j) = \int \exp(-n\psi_j(\boldsymbol{\beta})) d\boldsymbol{\beta}$ and the notation $\overline{\mathscr{I}}(\psi_j) = \int \exp(-n\overline{\psi}(\boldsymbol{\beta})) d\boldsymbol{\beta}$ so that $p(\mathbf{x}|\omega_j) = \mathscr{I}^j(\psi_j) / \overline{\mathscr{I}}(\overline{\psi})$.

An informal discussion of a method for approximating quantities such as $\mathscr{I}^j(\psi_j)$ and $\overline{\mathscr{I}}(\overline{\psi})$ is now provided. Let $\psi(\boldsymbol{\beta})$ be a smooth unimodal function whose gradient evaluated at the global minimizer $\hat{\boldsymbol{\beta}}$ vanishes. Expand $\psi(\boldsymbol{\beta})$ in a second-order Taylor series expansion about $\hat{\boldsymbol{\beta}}$ to obtain $\psi(\boldsymbol{\beta}) \approx \psi(\hat{\boldsymbol{\beta}}) + \frac{1}{2}(\boldsymbol{\beta} \hat{-} \boldsymbol{\beta})^T [\nabla^2 \psi(\hat{\boldsymbol{\beta}})](\boldsymbol{\beta} \hat{-} \boldsymbol{\beta})$ where $\nabla^2 \psi(\hat{\boldsymbol{\beta}})$ is positive definite because $\hat{\boldsymbol{\beta}}$ is a global minimizer. The integral $\mathscr{I}(\psi) = \int \exp(-n\psi(\boldsymbol{\beta})) d\boldsymbol{\beta}$ can be approximated by $\tilde{\mathscr{I}}(\psi) = \int \exp(-n[\psi(\hat{\boldsymbol{\beta}}) + \frac{1}{2}(\boldsymbol{\beta} \hat{-} \boldsymbol{\beta})^T [\nabla^2 \psi(\hat{\boldsymbol{\beta}})](\boldsymbol{\beta} \hat{-} \boldsymbol{\beta})]) d\boldsymbol{\beta}$ when the sample size n is sufficiently large (Tierney and Kadane, 1986). Note that since the integral of a multivariate Gaussian density with mean $\hat{\boldsymbol{\beta}}$ and covariance matrix $[n\nabla^2 \psi(\hat{\boldsymbol{\beta}})]^{-1}$ equals one we have

$$(2\pi)^{-q/2} (DET(n\nabla^2 \psi(\hat{\boldsymbol{\beta}})))^{1/2} \int \exp\left(-\frac{1}{2}(\boldsymbol{\beta} \hat{-} \boldsymbol{\beta})^T \times [n\nabla^2 \psi(\hat{\boldsymbol{\beta}})](\boldsymbol{\beta} \hat{-} \boldsymbol{\beta}) \right) d\boldsymbol{\beta} = 1 \quad [6]$$

Using the identity in eqn [6],

$$\hat{\mathscr{I}}(\psi) = \exp[-n\psi(\hat{\boldsymbol{\beta}})](2\pi)^{q/2}(DET(n\nabla^2\psi(\hat{\boldsymbol{\beta}})))^{-1/2} \quad [7]$$

Thus, $p(\mathbf{x}|\omega_j) \approx \hat{\mathscr{I}}(\psi_j)/\hat{\mathscr{I}}(\overline{\psi})$.

Predictive Approach with Nonparametric Bootstrap Simulation

A nonparametric bootstrap simulation method also called 'bagging' (Hastie et al., 2009) provides a simple simulation method for implementing the predictive approach.

- Step 1. Estimate a density $\hat{p}(\mathbf{y}|\mathscr{D}_n)$ for generating the observed data $\mathscr{D}_n$ by assigning a probability mass of $1/n$ to each of the original n observed data samples $\mathbf{y}_1, \ldots, \mathbf{y}_n$.
- Step 2. Let $b = 1$.
- Step 3. Sample n times with replacement from density $\hat{p}(\mathbf{y})$ to generate the bth bootstrap sample: $\mathbf{y}_1^b, \ldots, \mathbf{y}_n^b$.
- Step 4. Use $\mathbf{y}_1^b, \ldots, \mathbf{y}_n^b$ to compute an MLE or MAP estimate $\hat{\boldsymbol{\beta}}^b$.
- Step 5. Compute $\hat{p}^b(\mathbf{x}|\omega_j) = \frac{1}{b}\sum_{m=1}^{b} p(\mathbf{x}|\hat{\boldsymbol{\beta}}^m, \omega_j)$.
- Step 6. Let $b = b + 1$ and then go to step 3.

Predictive Approach with Parametric Bootstrap Simulation

- Step 1. Let $b = 1$.
- Step 2. Sample with replacement b times from $p(\boldsymbol{\beta}|\mathscr{D}_n)$ to obtain $\hat{\boldsymbol{\beta}}^1, \ldots, \hat{\boldsymbol{\beta}}^b$.
- Step 3. Compute $\hat{p}^b(\mathbf{x}|\omega_j) = \frac{1}{b}\sum_{m=1}^{b} p(\mathbf{x}|\hat{\boldsymbol{\beta}}^m, \omega_j)$.
- Step 4. Let $b = b + 1$ and then go to step 2.

As $b \to \infty$, $\hat{p}^b(\mathbf{x}|\omega_j) \to p(\mathbf{x}|\omega_j) = \int p(\mathbf{x}|\boldsymbol{\beta}, \omega_j)p(\boldsymbol{\beta}|\mathscr{D}_n)d\boldsymbol{\beta}$ under general conditions. However, implementing step 2 requires sampling from the a posteriori parameter density $p(\boldsymbol{\beta}|\mathscr{D}_n)$. This sampling process is typically computationally intractable so Monte Carlo Markov Chain methods such as Gibbs sampling or the Metropolis algorithms are often used to implement computationally tractable sampling algorithms (Hastie et al., 2009; Jackman, 2000).

Nonparametric and Parametric Learning Algorithms

Learning algorithms that make minimal assumptions regarding how the data was generated are referred to as nonparametric learning algorithms. For such algorithms, the parametric form of the class conditional density is often quite flexible. Nonparametric Parzen-window type learning algorithms e.g., (Duda et al., 2001; Hastie et al., 2009) essentially count the observed occurrence of different values of the feature vector $\mathbf{x}$. Learning algorithms that incorporate considerable prior knowledge about the data generating process are referred to as parametric learning algorithms. The classical Bayes classifier, which assumes that the class conditional densities are Gaussian, is a good example of a parametric learning algorithm (Duda et al., 2001; Patrick, 1972).

Nonparametric learning algorithms have the advantage of being relatively 'unbiased' in their analysis of the data but may require relatively large amounts of the right type of training data for effective learning. Moreover, despite the fact that nonparametric learning algorithms make minimal assumptions about the data, these minimal assumptions may still be incorrect. Parametric learning algorithms are 'biased' algorithms, but if the right type of prior knowledge is 'built-in' to the learning algorithm then a parametric learning algorithm can exhibit superior learning from even poor quality training data. Statistical pattern recognition algorithms that are typically viewed as 'nonparametric' can be transformed into parametric learning algorithms if a sufficient number of constraints upon the class conditional densities are imposed. For example, multilayer backpropagation neural network and perceptron-type learning algorithms (Duda et al., 2001; Golden, 1996; Hastie et al., 2009) can learn to approximate almost any desired form of the class conditional density function (given sufficiently many free parameters). Thus, such learning algorithms with large numbers of free parameters are naturally viewed as nonparametric statistical pattern recognition algorithms. On the other hand, the use of prior knowledge to construct the parametric form of the class conditional probability models results in parametric variations of such classical nonparametric learning algorithms. In other words, a multilayer backpropagation neural network learning algorithm is also naturally viewed as a parametric learning machine when the number of free parameters in such algorithms is constrained to be small (Golden, 1996).

Evaluation of Generalization Performance

In order to evaluate the performance of a statistical pattern recognition machine, it is not sufficient to report classification performance using the pattern vectors $\mathbf{y}_1, \ldots, \mathbf{y}_n$ that constitute the original data sample $\mathscr{D}_n$. The performance of a poorly designed statistical pattern recognition machine may be quite good on the original data sample $\mathscr{D}_n$ yet exhibit abysmal performance on new data that is not included in the original data sample $\mathscr{D}_n$.

One approach to this problem is to collect an additional data sample $\mathscr{D}'_n \equiv [\mathbf{y}'_1, \ldots, \mathbf{y}'_n]$ (called the 'test data') with the same number of pattern vectors as the original data sample $\mathscr{D}_n \equiv [\mathbf{y}_1, \ldots, \mathbf{y}_n]$. The original data sample $\mathscr{D}_n$, which is used to estimate the parameters of the model (and possibly specify the model architecture), is called the 'training data'. Classification results can then be reported using both the training data $\mathscr{D}_n$ and the test data $\mathscr{D}'_n$. Figure 2 illustrates the performance of a pattern recognition machine that does not evidence poor generalization performance. Notice that classification performance on the training data is consistently better than classification performance on the test data, yet this difference is relatively small in magnitude.

Figure 2 illustrates the performance of a poorly designed statistical pattern recognition machine applied to the same training and test data sets. Although the classification performance of the 'poor' machine on the training data appears superior to performance results of the 'good' machine on the training data, the performance of the 'poor' machine on the test data is very poor. These types of results are strong indicators that the poor statistical pattern recognition machine will exhibit poor generalization performance. A typical interpretation of the pattern of results shown in Figure 2 is that the poor pattern recognition machine has failed to learn crucial statistical regularities that are common to many different data samples but instead has learned 'statistical flukes' peculiar to the specific training data sample.

In practice, there are two major difficulties with using a training data and test data set approach. First, it is possible that crucial statistical regularities that are necessary for optimal

Figure 2 Evaluation of generalization performance in a statistical pattern recognition machine. In this example, the performance of the 'good' classifier evidences good classification performance on the training data, good classification performance on the test data, and good classification performance on a 'leave-one-out' cross-validation estimator using the training data. On the other hand, the performance of the 'poor' classifier is expected to exhibit poor generalization performance because it shows good classification performance on the training data yet poor classification performance on the test data and poor classification on the 'leave-one-out' cross-validation estimator on the training data.

learning are not present in the training data but are, in fact, present in the test data. Thus, learning performance might be improved by training the system with all the collected data. However, this would imply that there would not be a test data sample to support evaluation. Second, it is possible that all the crucial statistical regularities necessary for optimal learning are, in fact, in the original training data sample but the test data sample is not representative of a typical 'novel' data sample. Poor classification results on the test data sample in such a situation would thus be misleading. To address these issues, a number of approaches have been developed.

A widely used computationally intensive approach to addressing these problems is K-fold cross-validation (Hastie et al., 2009; pp. 214–216; Duda et al., 2001). The K-fold cross-validation method involves dividing the original data set $\mathscr{D}_n$ into K equal groups of observable data records. Next, $K-1$ of the groups are used as the training data and the remaining group of data is used as the test data. The classification performance statistics on the training and test data are then recorded. Next, a different choice of $K-1$ groups are defined as the training data, leaving the remaining group as the new test data group and again classification performance statistics on the training and test data recorded. Since there are K groups, this process can be repeated K times so that every one of the original K groups of data has the opportunity to be the test data group. The average and the standard deviation of the K 'training performance' and the K 'test performance' classification statistics are computed to, respectively, obtain estimators for test and training classification performance scores with standard errors. In the special case where the number of groups K is equal to the number of data samples n, then K-fold cross-validation is referred to as 'leave-one-out' cross-validation or 'jackknifing.' Figure 2 illustrates the ideas that even though the training data is used to compute the cross-validation estimator, the cross-validation estimator behaves in a manner that is similar to an estimator based upon 'test data.'

Another important approach for assessing generalization performance is called nonparametric bootstrapping (Hastie et al., 2009; pp. 214–221). An advantage of this approach over the K-fold cross-validation method is that the sample size of the training data and the sample size of the test data are both equal to the sample size n of the original data set. Training data performance is assessed simply by training the statistical pattern recognition machine using the original data sample $\mathscr{D}_n$ and recording the classification performance statistics. The mth nonparametric bootstrap data sample is generated by sampling n times with replacement from the original data sample $\mathscr{D}_n \equiv [\mathbf{y}_1, \ldots, \mathbf{y}_n]$ to obtain $\mathscr{D}_n^m = [\mathbf{y}_1^m, \ldots, \mathbf{y}_n^m]$, $m = 1, \ldots, b$. By construction then, a particular nonparametric bootstrap sample will typically omit some of the elements of the original data sample and have replications of other elements. The classification performance statistics are then computed from the mth nonparametric bootstrap sample. Nonparametric bootstrap classification performance estimators are obtained by computing the average and standard deviation of the b classification performance statistics from b nonparametric bootstrap samples. As $b \to \infty$, the average and standard deviation of the b classification performance statistics may be used to, respectively, estimate the nonparametric bootstrap classification performance estimator and its standard error. One difficulty with this form of the nonparametric bootstrap estimator is that parts of the training data may overlap with the test data. Hastie et al. (2009) review an approach for adjusting the estimator to compensate for this bias.

Applications

The number of applications of statistical pattern recognition is so diverse that any review cannot possibly do justice to indicating the range of applications (but see Jain et al., 2000; for a recent review). However, to provide some insights into the relevance of this area, a few arbitrary chosen examples of work in this area are provided.

Artificial Intelligence

Statistical pattern recognition methods have been extensively applied in the field of artificial intelligence. Successful applications of these methods in the field of computer vision include extraction of low-level visual information from visual images, edge detection, extracting shape information from shading information, object segmentation, and object labeling (e.g., Duda and Hart, 1973; Duda et al., 2001). Statistical pattern recognition methods such as hidden Markov models play an important role in speech recognition algorithms and natural language understanding (e.g., Duda et al., 2001). In the fields of robot control and neurocomputing, optimal control theory may be interpreted within a statistical pattern recognition framework where the control signal corresponds to the pattern recognition machine's 'action.'

Behavioral Modeling Applications

Econometricians and psychometricians make extensive use of statistical pattern recognition techniques for investigating the

behavior of individuals and groups of individuals. In addition, researchers have developed statistical pattern models of both human perceptual and human cognitive processes (Chater et al., 2006; Jacobs and Kruschke, 2011). Such probabilistic pattern recognition modeling applications include auditory–visual spatial integration, sensorimotor learning, associative learning, concept learning, multinomial processing tree cognitive process stage models, item response theory, multidimensional general recognition theory, psychometric cognitive diagnostic assessment, and language processing and language acquisition.

Data Analysis Applications

Classical statistical pattern recognition techniques such as factor analysis and principal component analysis, latent class modeling, latent and structural equation modeling, as well as other more general types of missing data analysis problems have been widely used by social scientists since their inception (Jackman, 2000; Raftery, 2001).

Statistical Pattern Recognition: Summary and Future Prospects

Most statistical pattern recognition systems consist of four major components. The first component is a feature selection and extraction stage where critical informational features about the data are identified for classification purposes. The second component is a probabilistic knowledge representation for representing the expected likelihood of particular features and the associated losses for making situation-specific decisions. The third component is a decision rule for making classification decisions that minimize an appropriate expected loss function. In many cases, a fourth component is required to learn the probabilistic knowledge representation from training data.

The computational goal of the learning process can be 'estimative' where parameters are estimated, or it can be 'predictive' where Bayesian methods are used to integrate out parameter effects. It is important to assess the performance of a statistical pattern recognition machine by using some combination of test data or cross-validation data. Important advantages of formulating behavioral and social models within a statistical pattern recognition framework include the availability of both existing and state-of-the-art methods for (1) making robust inferences in the presence of model misspecification (Golden, 2003; White, 1994) as well as model misspecification and missing data (Kashner et al., 2010), (2) comparing competing models (Golden, 2003), and (3) detecting the presence of model misspecification (Golden et al., 2013; White, 1994).

Statistical pattern recognition techniques are widely used in the fields of artificial intelligence and machine learning. In addition, such methods have been developed and widely used by social and behavioral scientists since their inception as well. Nevertheless, the field of statistical pattern recognition has so much to offer that methods of statistical pattern recognition remain underutilized in many fields including the social and behavioral sciences. For example, statistical pattern recognition methods such as linear regression or structural equation modeling are often applied without appropriate evaluations of generalization performance. As another example, missing data handling methods that are robust to the effects of model misspecification are rarely used. Continued efforts to more effectively utilize such methods not only will provide improved models in all areas of science and engineering (including the social and behavioral sciences) but also will additionally improve the quality of inferences for existing and future data.

Statistical Sufficiency

Nancy Reid, University of Toronto, Toronto, ON, Canada

© 2015 Elsevier Ltd. All rights reserved.

Abstract

In the language of statistical theory, a statistic is a function of a set of data, and a sufficient statistic contains as much information about the statistical model as the original set of data. Statistical sufficiency has served as a powerful concept in the theory of inference in helping to clarify the role of models and data and in providing a framework for data reduction.

Introduction

Statistical sufficiency is a concept in the theory of statistical inference that is meant to capture an intuitive notion of summarizing a large and possibly complex set of data by relatively few summary numbers that carry the relevant information in the larger data set. For example, a public opinion poll might sample one or two thousand people, but will typically report simply the number of respondents and the percentage of respondents in each of a small number of categories. A study to investigate the effectiveness of a new treatment for weight loss may well report simply the average weight loss of a group of patients receiving the new treatment. This study would usually report as well some measure of the range of weight loss observed; variability in this setting would be a crucial piece of information for evaluating the effectiveness of the new treatment.

In order to make precise the vague notion of an informative data summary, it is necessary to have a means of defining what we mean by relevant information. This in turn is highly dependent on the use we wish to make of the data. The formal mechanism for doing this is to use a *statistical model* to represent an idealized version of the problem we are studying. Statistical sufficiency and information are defined relative to this model. A statistical model is a family of probability distributions, the central problem of statistical inference being to identify which member of the family generated the data currently of interest. The basic concepts of statistical models and sufficiency were set out in Fisher (1922, 1925) and continue to play a major role in the theory of inference.

For example, we might in an idealized version of the weight loss problem assume that the potential weight loss can be described by a model in the family of *normal distributions*. This specifies a mathematical formula for the probability that the weight loss of an individual subject falls in any possible interval, and the mathematical formula depends on two unknown *parameters*, the mean and standard deviation. If we are willing to further assume that the same statistical model applies to all the potential recipients of the weight loss treatment, then the data collected in a careful study will enable us to make an inference on the two parameters that depends only on two data summaries: the average weight loss in the data and the standard deviation of the weight loss in the data.

The normal distribution is also referred to as the 'bell curve,' but there are in fact a family of bell curves, each differing from the other by a simple change of mean, which fixes the location of the bell curve, and standard deviation, which fixes the scale of the bell curve. Standardized tests for measuring IQ are designed so that the scores follow a bell curve model with parameter values for the mean and standard deviation of 100 and 15, respectively. The parameters for the potential weight loss under our hypothetical new treatment are unknown, and the role of the data collected on the treatment is to shed some light on their likely values. Should the weight loss bell curve turn out to be centered at or near zero, one would be wise not to invest too heavily in the new company's stock just yet. As long as we are willing to accept the bell curve model for the weight loss data, the information about that model is contained in two numbers: the average and the standard deviation of the weight loss recorded in our data set.

An idealized model that lies behind most media reporting of polls is a *Bernoulli* or *binomial* model, in which we assume that potential respondents will choose one of two categories with a fixed but unknown probability, that respondents choose categories independently of each other, and with the same, constant probability. In such an idealized version of the problem, we have complete information about this unknown probability from the number of responses and the proportion of responses in each of the two categories.

These two examples are by construction highly idealized, and it is easy to think quickly of a number of complexities that have been overlooked. An educated reader of a report on the weight loss study would want to know how the subjects were selected to receive the new treatment, whether the subjects were in any way representative of a population of interest to that reader, whether any comparison has been made with alternative, possibly conventional, treatments, the length of time over which the study was conducted, and so on. Public opinion polls typically offer more than two categories of response, even to a 'yes/no' question, including something equivalent to 'don't know,' or 'won't say,' and also often break down the results by gender, geographic area, or some other classification. Randomized selection of respondents by computerized telephone polls is much different than a reader response survey often conducted by magazines and media outlets. These and a wide variety of other issues are studied in the fields of experimental design and sample survey design, by statisticians and researchers in a variety of subject matter areas, from economics to geophysics. *See* Observational Studies: Overview; Sample Surveys: The Field and Methods; Experimental Design: Overview.

Statistical sufficiency is concerned with a much narrower issue, that of formalizing the notion that for a given family of models, a complex set of data can be summarized by a smaller

 http://dx.doi.org/10.1016/B978-0-08-097086-8.42178-1

collection of numbers, and lead to the same statistical inference. The following sections describe statistical sufficiency with reference to families of models and related concepts in the theory of statistics.

Statistical Models and Sufficiency

Basic Notation

We describe a statistical model by a *random variable* Y and a family of *probability distributions* for Y, $\mathcal{F}$. A random variable is a variable that takes values on a *sample space*, and a probability distribution describes the probability of observing a particular value or range of values in the sample space. The sample space is in a great many applications either *discrete*, taking values on a countable set such as (some subset of) the nonnegative integers, or *continuous* taking values on (some subset of) the real line $\mathbb{R}$ or p-dimensional Euclidean space $\mathbb{R}^p$. A typical data set will be a number of realizations of Y, and the goal is to use these observations to deduce which member of $\mathcal{F}$ generated these realizations. The members of $\mathcal{F}$ are often conveniently indexed by the probability mass function or probability density function $f(y)$, where

$$f(y) = \text{Prob}(Y = y) \qquad [1]$$

if the sample space is discrete, and

$$f(y) = \lim_{h \to 0} h^{-1}\{\text{Prob}(Y \le y + h) - \text{Prob}(Y \le y)\} \qquad [2]$$

if the sample space is continuous. If Y is a vector then Prob $(Y \le y)$ is defined component-wise as Prob $(Y_1 \le y_1, \ldots, Y_p \le y_p)$.

Very often the mathematical form of the probability distributions in $\mathcal{F}$ is determined up to a finite number of unknown constants called parameters, so we write $\mathcal{F}_\theta = \{f(\bullet;\theta); \theta \in \Theta\}$, where Θ is a set of possible values for θ, such as the real numbers $\mathbb{R}$, or real-valued vectors of fixed length p, $\mathbb{R}^p$, or [0, 1], and so on. The problem of using data to make an inference about the probability distribution is now the problem of making inference about the parameter θ, and is referred to as parametric inference. Sufficiency also plays a role in nonparametric inference as well, and we illustrate this at the end of this section.

We assume in what follows that the random variable $Y = (Y_1, \ldots, Y_n)$ is a vector of length n with observed value $y = (y_1, \ldots, y_n)$. A *statistic* is a function $T = t(Y)$ whose distribution can be computed from the distribution of Y. Examples of statistics include the average, $T_1 = n^{-1}\Sigma Y_i$, the sample variance $T_2 = (n-1)^{-1}\Sigma(Y_i - T_1)^2$, the standard deviation $T_3 = T_2^{1/2}$, the range $T_4 = \max Y_i - \min Y_i$, and so on. The probability distribution of any statistic is obtained from the probability distribution for Y by a mathematical calculation.

Sufficiency and Minimal Sufficiency

A statistic $T = t(Y)$ is sufficient for θ in the family of models $\mathcal{F} = \{f(y;\theta); \theta \in \Theta\}$ if and only if its conditional distribution

$$f_{Y|T}(y|t) \qquad [3]$$

does not depend on θ.

Example 1. Suppose $Y_1, \ldots Y_n$ are independent and identically distributed with probability mass function

$$f(y_i;\theta) = \theta^{y_i}(1-\theta)^{1-y_i}, \quad y_i = 0, 1; \quad \theta \in [0, 1] \qquad [4]$$

which can be used to model the number of successes in n independent Bernoulli trials, when the probability of success is θ. The joint density for $Y = (Y_1, \ldots, Y_n)$ is

$$f(y;\theta) = \prod \theta^{y_i}(1-\theta)^{1-y_i} = \theta^{\Sigma y_i}(1-\theta)^{n-\Sigma y_i} \qquad [5]$$

and the marginal density for $T = \Sigma Y_i$ is

$$f(t;\theta) = \sum_{y:\Sigma y_i = t} \theta^{\Sigma y_i}(1-\theta)^{n-\Sigma y_i} = \theta^t(1-\theta)^{n-t}c(t,n) \qquad [6]$$

where $c(t,n) = n!/t!\,(n-t)!$ is the number of vectors y of length n with t ones and $n-t$ zeroes. The conditional density of Y given T is the ratio of [5] and [6] and is thus free of θ.

The intuitive notion that the definition is meant to encapsulate is that once the sufficient statistic T is observed no further information about the θ is available from the original data Y.

The definition of sufficiency in terms of the conditional distribution is not very convenient to work with, especially in the case of continuous sample spaces where some care is needed in the definition of a conditional distribution. The following result is more helpful:

Factorization theorem: A statistic $T = t(Y)$ is sufficient for θ in the family of models $\mathcal{F} = \{f(y;\theta); \theta \in \Theta\}$ if and only if there exist functions $g(t;\theta)$ and $h(y)$ such that for all $\theta \in \Theta$

$$f(y;\theta) = g(t;\theta)h(y) \qquad [7]$$

Example 2. Let $Y_1, \ldots Y_n$ be independent, identically distributed from the normal distribution with mean μ and standard deviation σ:

$$f(y_i;\mu,\sigma) = \frac{1}{\sqrt{(2\pi)}\sigma}\exp\left\{-\frac{1}{2\sigma^2}(y_i-\mu)^2\right\} \qquad [8]$$

The joint density of $Y = (Y_1, \ldots Y_n)$ is

$$f(y;\mu,\sigma) = \left(\frac{1}{\sqrt{2\pi}\sigma}\right)^n \exp\left\{-\frac{1}{2\sigma^2}\sum(y_i-\mu)^2\right\},$$
$$= \frac{1}{\sigma^n}\exp\left\{-\frac{1}{2\sigma^2}\sum(y_i-\bar{y})^2 + \frac{n}{2\sigma^2}(\bar{y}-\mu)^2\right\}\left(\frac{1}{\sqrt{2\pi}}\right)^n \qquad [9]$$

where $\bar{y} = n^{-1}\Sigma y_i$ is the sample average, $\theta = (\mu, \sigma)$, and $\Theta = \Re \times \Re^+$. From [9] we see that $T = \{\bar{Y}, \sum(Y_i - \bar{Y})^2\}$ is sufficient for θ, with $g(t;\theta)$ identified with all but the final factor in [9].

Strictly speaking, there are a number of other sufficient statistics in both the examples above. In Example 2, $(\sum_1^4 Y_i, \sum_5^n Y_i, \sum_1^7 (Y_i - \bar{Y})^2, \sum_8^n (Y_i - \bar{Y})^2)$ is also sufficient, as is, trivially, the original vector Y itself. Clearly $(\bar{Y}, \sum_1^n (Y_i - \bar{Y})^2)$ is in some sense 'smaller' than these other sufficient statistics, and to be preferred for that reason. A *minimal sufficient statistic* is defined to be a function of every other sufficient statistic. One-to-one functions of the minimal sufficient statistic are also minimal sufficient and are not distinguished, so in Example 2, $(\sum_1^n Y_i, \sum_1^n Y_i^2)$ is also minimal sufficient. Any statistic defines a partition of the sample space in which all sample points leading to the same value of the statistic fall in the

same partition, and the minimal sufficient statistic defines the coarsest possible partition.

Since the central problem of parametric statistical inference is to reason from the data back to the parameter θ, extensive use is made of the *likelihood function*, which is (proportional to) the joint density of the data, regarded as a function of θ:

$$L(\theta; y) = c(y) f(y; \theta) \qquad [10]$$

See Likelihood in Statistics. The factorization theorem suggests, and it can be proved, that the minimal sufficient statistic in the family of models $\mathcal{F}$ is the likelihood statistic $L(\cdot; Y)$. This result is easily derived from the factorization theorem if Θ is a finite set, but extending it to cases of more practical interest involves some mathematical intricacies (Barndorff-Nielsen, 1978: Chapter 4; Fraser and Naderi, 2007). *See* Likelihood Function and Maximum Likelihood Estimation.

Example 3. To illustrate the concept of sufficiency in a nonparametric setting, suppose that $Y_1, \ldots, Y_n$ are independent, identically distributed on $\mathbb{R}$ with probability density function f; i.e., $\mathcal{F}$ consists of all probability distributions which have densities with respect to Lebesgue measure. Denote by $Y_{(\cdot)}$ the vector of ordered values $Y_{(\cdot)} = (Y_{(1)} \le Y_{(2)} \le \ldots \le Y_{(n)})$. Then $Y_{(\cdot)}$ is sufficient for $\mathcal{F}$, as

$$f_{Y|Y(\cdot)}(y|y_{(\cdot)}) = \begin{cases} \dfrac{1}{n!} & \text{if y is a permutation of } y_{(\cdot)} \\ 0 & \text{otherwise} \end{cases} \qquad [11]$$

is the same for all members of $\mathcal{F}$.

Example 4. Let $Y_1, \ldots, Y_n$ be independent, identically distributed according to the uniform distribution on $(\theta - 1, \theta + 1)$, where $\theta \in \mathbb{R}$. The order statistic $Y_{(\cdot)}$ is sufficient, as this is a special case of Example 3 above, but is not minimal sufficient. The minimal sufficient statistic is determined from the likelihood function:

$$L(\theta; y) = \begin{cases} \displaystyle\prod_{i=1}^{n} \left(\frac{1}{2}\right) & \text{if } y_{(n)} - 1 \le \theta \le y_{(1)} + 1 \\ 0 & \text{otherwise} \end{cases} \qquad [12]$$

from which we see that the minimal sufficient statistic is $T = (Y_{(1)}, Y_{(n)})$, as this is a one to one function of the likelihood statistic.

Exponential Families

A random vector $Y \in \mathbb{R}^p$ is said to be distributed according to an exponential family of dimension k if the probability mass or density function can be expressed in the form

$$f(y; \theta) = \exp\left\{\varphi(\theta)^T t(y) - c(\theta) - d(y)\right\} \qquad [13]$$

for some functions $\varphi(\theta) = \{\varphi_1(\theta), \ldots, \varphi_k(\theta)\}$, $t(y) = \{t_1(y), \ldots, t_k(y)\}$, $c(\theta)$, and $d(y)$.

Many common distributions can be expressed in exponential family form, including Example 1 with $\varphi(\theta) = \log\{\theta/(1-\theta)\}$, $t(y) = \sum y_i$ and Example 2 with

$$\varphi(\theta) = \left(\frac{\mu}{\sigma}, -\frac{1}{2\sigma^2}\right), \quad t(y) = \left(\sum y_i, \sum y_i^2\right) \qquad [14]$$

Other examples of exponential families include the Poisson, geometric, negative binomial, multinomial, exponential, gamma, and inverse Gaussian distributions. Generalized linear models are regression models built on exponential families that have found wide practical application. *See* Analysis of Variance; Generalized Linear Models.

From [13] we can see that exponential families are closed under independent, identically distributed sampling, and that the minimal sufficient statistic for θ is the k-dimensional vector $T = \sum t(Y_i)$. Exponential families are said to permit a *sufficiency reduction* under sampling; we can replace the original n observations by a vector of length k. Possibly for this reason exponential families are widely used as models in applied work.

A partial converse of this is also true, that if a finite dimensional minimal sufficient statistic exists in independent sampling from the same density, and the range of values over which the density is positive does not depend on θ, then that density must be of exponential family form.

Versions of the material in this appear in most mathematical statistics textbooks. Suggested references, roughly in order of increasing difficulty, are Azzalini (1996), Casella and Berger (1990), Lehmann and Casella (1998), Cox and Hinkley (1974), Pace and Salvan (1997), and Barndorff-Nielsen and Cox (1994). Generalized linear models are treated in Dobson (2001) and McCullagh and Nelder (1989).

Some Related Concepts

Ancillary Statistics

A companion concept for the reduction of data to a number of smaller quantities is that of *ancillarity*. A statistic $A = a(Y)$ is said to be ancillary for θ in the family of models $\mathcal{F}$ if the marginal distribution of A

$$f_A(a) = \int_{\{y; a(y) = a\}} f(y; \theta) \mathrm{d}y \qquad [15]$$

is free of θ. If every other ancillary statistic is a function of a given ancillary statistic, the given statistic is a maximal ancillary statistic.

Example 4 cont'd: In independent sampling from the $U(\theta, \theta + 1)$ distribution, $T = (Y_{(1)}, Y_{(n)})$ is a minimal sufficient statistic and $A = Y_{(n)} - Y_{(1)}$ is a maximal ancillary statistic.

If an ancillary statistic exists all the information about θ is in the conditional distribution of Y, given the ancillary statistic. If a minimal sufficient statistic exists, all the information about θ is in the marginal distribution of T. These two data reductions, to A or to T, are complementary, and can sometimes be combined.

Example 5: Let $Y_1, \ldots, Y_n$ be independent, identically distributed from the one parameter *location* family $f(y_i; \theta) = f_0(y_i - \theta)$, $\theta \in \mathbb{R}$, where $f_0(\cdot)$ is known. Then the vector of residuals $A = (Y_1 - \overline{Y}, \ldots, Y_n - \overline{Y})$ is ancillary. An extension of this to the location scale family is possible: let $f(y_i; \theta) = \sigma^{-1} f_0\{\sigma^{-1}(y_i - \mu)\}$, then

$$A = \left\{(Y_1 - \overline{Y})/S, \ldots, (Y_n - \overline{Y})/S\right\} \qquad [16]$$

where $S^2 = \sum (Y_i - \overline{Y})^2$ is a maximal ancillary. The normal distribution of Example 4 is a location-scale model, with minimal sufficient statistic $T = (\overline{Y}, S^2)$, which in this case is independent of A.

A result due to Basu (1964) is that a sufficient statistic that is boundedly complete is independent of any ancillary statistic. Bounded completeness of a sufficient statistic is a technical condition that is occasionally useful in obtaining optimality results, particularly with respect to minimum variance unbiased estimation, a topic that is somewhat out of fashion.

The importance for the theory of statistics in concepts of dimension reduction such as ancillarity and sufficiency is that inference for a k-dimensional parameter is encapsulated by a probability distribution on a k-dimensional space. This immediately provides tests of significance, confidence intervals, and point estimates for the unknown parameter. From this point of view, it now appears that ancillarity is possibly a more central notion to the theory of statistics, although sufficiency is widely regarded as more natural and intuitive.

It should be noted that inference from a Bayesian point of view automatically provides a k-dimensional distribution for inference for a k-dimensional parameter, which is the posterior distribution given the observed data y. This is achieved at the expense of constructing a probability model for the unknown parameter θ. *See* Bayesian Statistics.

Asymptotic Sufficiency

The normal distribution is widely used for modeling data from a variety of sources, but is also very important in the theory of inference in providing approximate inferences, when exact inferences may be unavailable. While the likelihood function is equivalent to the minimal sufficient statistic, a special role in approximate inference is played by some functions computed from the likelihood function.

The maximum likelihood estimator of θ in the model $f(y;\theta)$ is defined by.

$$\sup_{\theta} L(\theta;y) = L\left(\widehat{\theta};y\right) \qquad [17]$$

and the observed and expected information functions for θ are

$$j(\theta) = -\partial^2\left[\log\{L(\theta;y)\}\right]/\partial\theta\partial\theta', \quad i(\theta) = \mathrm{E}\{j(\theta)\} \qquad [18]$$

Under regularity conditions on the family of models for $Y=(Y_1,\ldots,Y_n)$, we have the following asymptotic result for a scalar parameter θ as $n \to \infty$:

$$\left(\widehat{\theta}-\theta_0\right)i^{1/2}(\theta_0) \xrightarrow{d} N(0,1) \qquad [19]$$

which means that for sufficiently large n, the distribution of the maximum likelihood estimator is arbitrarily close to a normal distribution with mean zero and variance $i^{-1}(\theta_0)$, under sampling from $f(y;\theta_0)$. A similar result is available for vector parameters. Usually in practice, the asymptotic variance of $\widehat{\theta}$ will be estimated by $j^{-1}(\widehat{\theta})$.

The maximum likelihood estimator has by construction the same dimension as the unknown parameter θ, so [19] provides a means of constructing an inference for θ using the normal approximation. This suggests that a notion of *asymptotic sufficiency* could be formalized, the maximum likelihood estimator having this property. This formalization relies on showing that the likelihood function is asymptotically of normal form, with minimal sufficient statistic $\widehat{\theta}$; see Fraser (1976: Chapter 8). The argument is very similar to that showing that the posterior distribution for θ is asymptotically normal. More generally, in models with smooth likelihood functions, a Taylor series expansion of the likelihood function around $\widehat{\theta}$ suggests a refinement of asymptotic sufficiency: the set of statistics $\widehat{\theta}$ and second and higher order derivatives of the likelihood function evaluated at $\widehat{\theta}$ form a set of approximately sufficient statistics in a certain sense (Barndorff-Nielsen and Cox, 1994: Chapter 7).

In general models, the maximum likelihood estimator is not the minimal sufficient statistic, although it is always a (many-to-one) function of the minimal sufficient statistic. Much of the recent development of the parametric theory of inference has been concerned with combining sufficiency or approximate sufficiency with ancillarity or an appropriate notion of approximate ancillarity, to effect a dimension reduction with minimal loss of information. In general models if the maximum likelihood estimator is used in place of the minimal sufficient statistic, information is lost. The idea of recovering this information, via conditioning on an ancillary statistic, was put forth in Fisher (1934). With some exceptions this idea was not fully exploited in the statistical literature until about 1980, when it was discovered that an asymptotic version of Fisher's argument holds in very general situations. The past 20 years have seen continued development and refinement of Fisher's original idea. A brief overview is given in Reid (2000), and the books Barndorff-Nielsen and Cox (1994) and Pace and Salvan (1997) give detailed accounts.

Inference in the Presence of Nuisance Parameters

Many statistical models have vector valued parameters θ, but often some components or scalar valued functions of θ are of particular interest. For example, in evaluating the hypothetical new weight loss treatment under a normal model, the mean parameter μ is in the first instance of more interest than the standard deviation σ. In studying results from a poll, we may wish to introduce parameters describing various aspects of the population, such as gender, age group, income bracket, and so on, but the main purpose of the poll is to construct an inference about the proportion likely to vote for our candidate, for example.

The idealized modeling of these types of situations is to describe θ as consisting of two components $\theta=(\psi,\ \lambda)$, of *parameters of interest*, ψ, and *nuisance parameters*, λ. An extension of this would be to define $\psi=g(\theta)$ as determined by a set of constraints on θ, but only the component version will be considered here.

There are in the literature several different definitions of sufficiency for a parameter of interest ψ in the presence of a nuisance parameter λ. To illustrate some of the issues we consider again the normal distribution with $\theta=(\mu,\ \sigma)$, $T = (\overline{Y}, S^2)$. We have

$$f_T(t;\mu,\sigma) = f_{\overline{Y}}(\overline{y};\mu,\sigma)f_{S^2|Y}\left(s^2;\sigma^2\right), = f_{\overline{Y}}(\overline{y};\mu,\sigma)f_{S^2}\left(s^2;\sigma^2\right) \qquad [20]$$

where $f_{\overline{Y}}(\cdot)$ is the density of a normal distribution with mean μ and standard deviation σ/n, and $f_{S^2}(\cdot)$ is proportional to that of a chi-squared distribution on $n-1$ degrees of freedom. As the conditional distribution of S^2, given $\overline{Y}$ is free of μ, we could define $\overline{Y}$ as sufficient for μ, by analogy to [3]. However, it is not sufficient for μ in the sense of providing everything we need for

inference about μ, since its distribution depends also on σ. In this latter sense S^2 is sufficient for σ.

There have been a number of attempts to formalize the notions of partial sufficiency and partial ancillarity, but none has been particularly successful. However, the notion of dimension reduction through exact or approximate sufficiency and ancillarity has played a very important role in the theory of parametric inference.

Sufficiency in the presence of nuisance parameters is considered in Barndorff-Nielsen (1978: Chapter 4), Jorgensen (1997), and Bhapkar (1991). A discussion of partitions like [20] and the role of conditional and marginal inference is given in Reid (1995). *See* Likelihoods that Eliminate Nuisance Parameters.

Complex Models

In some applications, the model is too complex to enable a likelihood function to be constructed; it may entail a large number of integrals over latent random variables, for example. Several approaches to inference in such settings involve computing some version of approximate likelihoods, either by simulation, or by ignoring some higher-order dependencies. Two examples of these approaches are the method of indirect inference (Gouriéroux and Montfort, 1996) and approximate Bayesian computation (ABC) (Marin et al., 2011); the latter is focused on Bayesian inference, but may be useful for approximate likelihood inference as well. Since the likelihood map is sufficient, this might suggest that there is no role for the concept of sufficiency or approximate sufficiency in such settings, but Robert et al. (2011) show that the ABC method will not be consistent for model selection unless it is built on sufficient statistics for the model of interest. Indirect inference also uses sufficient statistics, although for an auxiliary model, as a step in simulating the likelihood of the model of interest. Connections between indirect inference and ABC methods are mentioned in Fearnhead and Prangle (2011) and a subject of ongoing research.

Conclusion

A sufficient statistic is defined relative to a statistical model, usually a parametric model, and provides all the information in the data about that model or the parameters of that model. In many cases, the sufficient statistic provides a substantial reduction of complexity or dimension from the original data, and as a result the concept of sufficiency makes the task of statistical inference simpler. The related concept of ancillarity has a similar function. Recent developments in likelihood inference have emphasized the construction of approximately sufficient and approximately ancillary statistics in cases where further dimension reduction is needed after invoking sufficiency and ancillarity. Excellent textbook references for the definitions and examples include Casella and Berger (1990) and Azzalini (1996). More advanced accounts of recent work are given in Barndorff-Nielsen and Cox (1994) and Pace and Salvan (1997).

Abstract

The history of statistics can be told in several ways: as a quantitative description of the social world, or as a branch of applied mathematics making it possible to build models in any area featuring large numbers. There are many historical connections between these narratives. This history began in the eighteenth century, with German '*Statistik*' and English *political arithmetic*. In the nineteenth century Quetelet established a relation between the probabilistic theory of the 'average man' and the gathering of official statistics by governments, with a large use of the Gaussian distribution and of the relative stability of macrosocial phenomena. In the 1890s, Francis Galton and Karl Pearson created a mathematical theory of statistical distribution, and introduced the ideas of variance, regression, correlation, and chi-square test. That theory was then developed by Ronald Fisher, Jerzy Neyman, and Egon Pearson, with the inferential statistics theory, giving a strong probabilistic foundation to estimation, tests, maximum likelihood, and sampling theory. Simultaneously, official statistical bureaux, compiling administrative statistics, and organising censuses and sampling surveys, were also developed. These institutions, often perceived only as suppliers of data assumed to reflect reality, are also places where this reality is instituted through co-constructed operations of social representations, public action, and statistical measurement.

The word 'statistics' today has several different meanings. For the public, and even for many people specializing in social studies, it designates numbers and measurements relating to the social world: population, gross national product, and unemployment, for instance. For academics in 'Statistics Departments,' however, it designates a branch of applied mathematics making it possible to build models in any area featuring large numbers, not necessarily dealing with society. History alone can explain this dual meaning. Statistics appeared at the beginning of the nineteenth century as meaning a 'quantified description of human–community characteristics.' It brought together two previous traditions: that of German '*Statistik*' and that of English *political arithmetic* (Lazarsfeld, 1977).

When it originated in Germany in the seventeenth and eighteenth centuries, the *Statistik* of Hermann Conring (1606–81) and Gottfried Achenwall (1719–79) was a means for classifying the knowledge needed by kings. This 'science of the state' included history, law, political science, economics, and geography, that is, a major part of what later became the subjects of 'social studies,' but presented from the point of view of their utility for the state. These various forms of knowledge did not necessarily entail quantitative measurements: they were basically associated with the description of specific territories in all their aspects. This territorial connotation of the word 'statistics' would subsist for a long time in the nineteenth century.

Independently of the German *Statistik*, the English tradition of political arithmetic had developed methods for analyzing numbers and calculations, on the basis of parochial records of baptisms, marriages, and deaths. Such methods, originally developed by John Graunt (1620–74) in his work on 'bills of mortality,' were then systematized by William Petty (1627–87). They were used, among others, to assess the population of a kingdom and to draw up the first forms of life insurance. They constitute the origin of modern demography.

Nineteenth-century 'statistics' were therefore a fairly informal combination of these two traditions: taxonomy and numbering. At the beginning of the twentieth century, it further became a mathematical method for the analysis of facts (social or not) involving large numbers and for inference on the basis of such collections of facts. This branch of mathematics is generally associated with the *probability theory*, developed in the seventeenth and eighteenth centuries, which, in the nineteenth century, influenced many branches of both the social and natural sciences (Gigerenzer et al., 1989). The word 'statistics' is still used in both ways today and both of these uses are still related, of course, insofar as quantitative social studies use, in varied proportions, inference tools provided by mathematical statistics. The probability calculus, on its part, grounds the credibility of statistical measurements resulting from surveys, together with random sampling and confidence intervals.

The diversity of meanings of the word 'statistics,' maintained until today, has been heightened by the massive development, beginning in the 1830s, of *bureaus of statistics*, administrative institutions distinct from universities, in charge of collecting, processing, and transmitting quantified information on the population, the economy, employment, living conditions, etc. Starting in the 1940s, these bureaus of statistics became important 'data' suppliers for empirical social studies, then in full growth. Their history is therefore an integral part of these sciences, especially in the second half of the twentieth century, during which the mathematical methods developed by university statisticians were increasingly used by the so-called 'official' statisticians. Consequently the 'history of statistics' is a crossroads history connecting very different fields, which are covered in other articles of this encyclopedia: general problems of the quantification' of social studies (Theodore Porter), mathematical 'sampling' methods (Stephen E. Fienberg and J. M. Tanur), ' survey research' (Martin Bulmer), ' demography' (Simon Szreter), 'econometrics,' etc. The history of these different fields was the object of much research in the 1980s

and 1990s, some examples of which are indicated in the Bibliography. Its main interest is to underscore the increasingly closer connections between the so-called 'internal' dimensions (history of the technical tools), the 'external' ones (history of the institutions), and those related to the construction of social studies 'objects,' born from the interaction between the three foci constituted by university research, administrations in charge of 'social problems,' and bureaus of statistics. This 'co-construction' of objects makes it possible to join historiographies that not long ago were distinct. Three key moments of this history will be mentioned here: Adolphe Quetelet and the average man (1830s), Karl Pearson and correlation (1890s), and the establishment of large systems for the production and processing of statistics.

Quetelet, the Average Man, and Moral Statistics

The cognitive history of statistics can be presented as that of the tension and sliding between two foci: the *measurement of uncertainty* (Stigler, 1986), resulting from the work of eighteenth-century astronomers and physicists, and the *reduction of diversity*, which will be taken up by social studies. Statistics is a way of taming chance (Hacking, 1990) in two different ways: chance and uncertainty related to protocols of observation, chance and dispersion related to the diversity and the indetermination of the world itself. The Belgian astronomer and statistician Adolphe Quetelet (1796–1874) is the essential character in the transition between the world of 'uncertain measurement' of the probability proponents (Carl Friedrich Gauss, Pierre Simone de Laplace) and that of the 'regularities' resulting from diversity, thanks to his having transferred, around 1830, the concept of average from the natural sciences to the human sciences, through the construction of a new being, the average man.

As early as the eighteenth century, specificities appeared from observations in large numbers: drawing balls out of urns, gambling, successive measurements of the position of a star, sex ratios (male and female births), or the mortality resulting from preventive smallpox inoculation, for instance. The radical innovation of this century was to connect these very different phenomena thanks to the common perspective provided by the 'law of large numbers' formulated by Jacques Bernoulli in 1713. If draws from a constant urn containing white and black balls are repeated a large number of times, the observed share of white balls 'converges' toward that actually contained by the urn. Considered by some as a mathematical theorem and by others as an experimental result, this 'law' was at the crossroads of the two currents in epistemological science: one 'hypothetical deductive,' the other 'empirical inductive.'

Beginning in the 1830s, the statistical description of 'observations in large numbers' became a regular activity of the state. Previously reserved for princes, this information henceforth available to 'enlightened men' was related to the population, to births, marriages, and deaths, to suicides and crimes, to epidemics, to foreign trade, schools, jails, and hospitals. It was generally a by-product of administration activity, not the result of special surveys. Only the population census, the showcase product of nineteenth-century statistics, was the object of regular surveys. These statistics were published in volumes with heterogeneous contents, but their very existence suggests that the characteristics of society were henceforth a matter of scientific law and no longer of judicial law, that is, of observed regularity and not of the normative decisions of political power. Quetelet was the man who orchestrated this new way of thinking the social world. In the 1830s and 1840s, he set up administrative and social networks for the production of statistics and established – until the beginning of the twentieth century – how statistics were to be interpreted.

This interpretation is the result of the combination of two ideas developed from the law of large numbers: the generality of 'normal distribution' (or, in Quetelet's vocabulary: the 'law of possibilities') and the regularity of certain yearly statistics. As early as 1738, Abraham de Moivre, seeking to determine the convergence conditions for the law of large numbers, had formulated the mathematical expression of the future 'Gaussian law' as the limit of a binomial distribution. Then Laplace (1749–1827) had shown that this law constituted a good representation of the distribution of measurement errors in astronomy, hence the name that Quetelet and his contemporaries also used to designate it: the law of errors (the expression 'normal law,' under which it is known today, would not be introduced until the late nineteenth century by Karl Pearson).

Quetelet's daring intellectual masterstroke was to bring together two forms: on the one hand the law of errors in observation, and on the other, the law of distribution of certain body measurements of individuals in a population, such as the height of conscripts in a regiment. The likeness of the 'Gaussian' looks of these two forms of distribution justified the invention of a new being with a promise of notable posterity in social studies: the average man. Thus, Quetelet restricted the calculation and the legitimate use of averages to cases where the distribution of the observations had a Gaussian shape, analogous to that of the distribution of the astronomical observations of a star. Reasoning on that basis, just as previous to this distribution there was a real star (the 'cause' of the Gaussian-shaped distribution), previous to the equally Gaussian distribution of the height of conscripts there was a being of a reality comparable to the existence of the star. Quetelet's average man is also the 'constant cause,' previous to the observed controlled variability. He is a sort of model, of which specific individuals are imperfect copies.

The second part of this cognitive construction, which is so important in the ulterior uses of statistics in social studies, is the attention drawn by the 'remarkable regularity' of series of statistics, such as those of marriages, suicides, or crimes. Just as series of draws from an urn reveal a regularity in the observed frequency of white balls, the regularity in the rates of suicide or crime can be interpreted as resulting from series of draws from a population, some of the members of which are affected with a 'propensity' to suicide or crime. The average man is therefore endowed not only with physical attributes but also 'moral' ones, such as these propensities. Here again, just as the average heights of conscripts are stable, whereas individual heights are dispersed, crime or suicide rates are just as stable, whereas these acts are eminently individual and unpredictable. This form of statistics, then called 'moral,' signaled the beginning of sociology, a science of society radically distinct from a science of the

individual, such as psychology (Porter, 1986). Quetelet's reasoning would ground the one developed by Durkheim in *Suicide: A Study in Sociology* (1897).

This way of using statistical regularity to back the idea of the existence of a society ruled by specific 'laws,' distinct from those governing individual behavior, dominated nineteenth-century, and, in part, twentieth-century social studies. Around 1900, however, another approach appeared, this one centered on two ideas: the distribution (no longer just the average) of observations, and the correlation between two or several variables, observed in individuals (no longer just in groups, such as territories).

Distribution, Correlation, and Causality

This shift of interest from the average individual to the distributions and hierarchies among individuals, was connected to the rise, in late-century Victorian England, of a eugenicist and hereditarian current of thought inspired from Darwin (MacKenzie, 1981). Its two advocates were Francis Galton (1822–1911), a cousin of Darwin, and Karl Pearson (1857–1936). In their attempt to measure biological heredity, which was central to their political construction, they created a radically new statistics tool that made it possible to conceive partial causality. Such causality had been absent from all previous forms of thought, for which A either is or is not the cause of B, but cannot be so somewhat or incompletely. Yet Galton's research on heredity led to such a formulation: the parents' height 'explains' the children's, but does not entirely 'determine' it. The taller fathers are, the taller are their sons *on average*, but, for a father's given height, the sons' height dispersion is great. This formalization of heredity led to the two related ideas of regression and correlation, later to be extensively used in social studies as symptoms of causality.

Pearson, however, greatly influenced by the antirealist philosophy of the physicist Ernst Mach, challenged the idea of 'causality,' which according to him was 'metaphysical,' and stuck to the one of 'correlation,' which he described with the help of 'contingency tables' (Pearson, 1911: Chap. 5). For him, scientific laws are only summaries, brief descriptions in mental stenography, abridged formulas, a condensation of perception routines for future use and forecasting. Such formulas are the limits of observations that never perfectly respect the strict functional laws. The correlation coefficient makes it possible to measure the strength of the connection, between zero (independence) and one (strict dependence). Thus, in this conception of science associated by Pearson with the budding field of mathematical statistics, the reality of things can only be invoked for pragmatic ends and provided that the 'perception routines' are maintained. Similarly, 'causality' can only be insofar as it is a proven correlation, therefore predictable with a fairly high probability. Pearson's pointed formulations would constitute, in the early twentieth century, one of the foci of the epistemology of statistics applied to social studies. Others, in contrast, would seek to give new meaning to the concepts of reality and causality by defining them differently. These discussions were strongly related to the aims of the statistical work, strained between scientific knowledge and decisions.

Current mathematical statistics proceed from the works of Karl Pearson and his successors: his son Egon Pearson (1895–1980), the Polish mathematician Jerzy Neyman (1894–1981), the statistician pioneering in agricultural experimentation Ronald Fisher (1890–1962), and finally the engineer and beer brewer William Gosset, alias Student (1876–1937). These developments were the result of an increasingly thorough integration of so-called 'inferential' statistics into probabilistic models. The interpretation of these constructions is always stretched between two perspectives: the one of science, which aims to prove or test hypotheses, with truth as its goal, and the one of action, which aims to make the best decision, with efficiency as its goal. This tension explains a number of controversies that opposed the founders of inferential statistics in the 1930s. In effect, the essential innovations were often directly generated within the framework of research as applied to economic issues, for instance in the cases of Gosset and Fisher.

Gosset was employed in a brewery. He developed product quality-control techniques based on a small number of samples. He needed to appraise the variances and laws of distribution of parameters calculated on observations not complying with the supposed ' law of large numbers.' Fisher, who worked in an agricultural research center, could only carry out a limited number of controlled tests. He mitigated this limitation by artificially creating a randomness, itself controlled, for variables other than those for which he was trying to measure the effect. This 'randomization' technique thus introduced probabilistic chance into the very heart of the experimental process. Unlike Karl Pearson, Gosset and Fisher used distinct notations to designate, on the one hand, the theoretical parameter of a probability distribution (a mean, a variance, a correlation) and on the other, the estimate of this parameter, calculated on the basis of observations so insufficient in number that it was possible to disregard the gap between these two values, theoretical and estimated.

This new system of notation marked a decisive turning point: it enabled an inferential statistics based on probabilistic models. This form of statistics was developed in two directions. The estimation of parameters, which took into account a set of recorded data, presupposed that the model was true. The information produced by the model was combined with the data, but nothing indicated whether the model and the data were in agreement. In contrast, the hypothesis tests allowed this agreement to be tested and if necessary to modify the model: this was the inventive part of inferential statistics. In wondering whether a set of events could plausibly have occurred if a model were true, one compared these events – explicitly or otherwise – to those that would have occurred if the model were true, and made a judgment about the gap between these two sets of events.

This judgment could itself be made according to two different perspectives, which were the object of vivid controversy between Fisher on the one hand, and Neyman and Egon Pearson on the other. Fisher's test was placed in a perspective of truth and science: a theoretical hypothesis was judged plausible or was rejected, after consideration of the observed data. Neyman and Pearson's test, in contrast, was aimed at decision making and action. One evaluated the respective costs of accepting a false hypothesis and of rejecting a true one,

described as errors of Type I and II. These two different aims – truth and economy – although supported by close probabilistic formalism, led to practically incommensurable argumentative worlds, as was shown by the dialogue of the deaf between Fisher on one side, and Neyman and Pearson on the other (Gigerenzer et al., 1989: pp. 90–109).

Official Statistics and the Construction of the State

At the same time as mathematical statistics were developing, so-called 'official' statistics were also being developed in 'bureaus of statistics,' for a long time on an independent course. These latter did not use the new mathematical tools until the 1930s in the United States and the 1950s in Europe, in particular when the random sample-survey method was used to study employment or household budgets. Yet in the 1840s, Quetelet had already actively pushed for such bureaus to be set up in different countries, and for their 'scientification' with the tools of the time. In 1853, he had begun organizing meetings of the International Congress of Statistics,' which led to the establishment in 1885 of the 'International Statistical Institute' (which still exists and includes mathematicians and official statisticians). One could write the history of these bureaus as an aspect of the more general history of the construction of the state, insofar as they developed and legitimized a common language specifically combining the authority of science and that of the state (Anderson 1988; Desrosiéres 1998; Patriarca 1996).

More precisely, every period of the history of a state could be characterized by the list of 'socially judged social' questions that were consequently put on the agenda of official statistics. So were co-constructed three interdependent foci: representation, action, and statistics – a way of describing and interpreting social phenomena (to which social studies would increasingly contribute), a method for determining state intervention and public action, and finally, a list of statistical 'variables' and procedures aimed at measuring them.

Thus for example in England in the second third of the nineteenth century, poverty, mortality, and epidemic morbidity were followed closely in terms of a detailed geographical distribution (counties) by the General Register Office (GRO), set up by William Farr in 1837. England's economic liberalism and the Poor Law Amendment Act of 1834 (which led to the creation of workhouses) were consistent with this form of statistics. In the 1880s and 1890s, Galton and Pearson's hereditarian eugenics would compete with this 'environmentalism,' which explained poverty in terms of the social and territorial contexts. This new 'social philosophy' was reflected in news forms of political action, and of statistics. Thus the 'social classification' in five differentiated groups used by British statisticians throughout the twentieth century is marked by the political and cognitive configuration of the beginning of the century (Szreter 1996).

In all the important countries (including Great Britain) of the 1890s and 1900s, however, the work of the bureaus of statistics was guided by labor-related issues: employment, wages, workers' budgets, subsistence costs, etc. The modern idea of unemployment emerged, but its definition and its measurement were not standardized yet. This interest in labor statistics was linked to the fairly general development of a specific 'labor law' and the first so-called 'social welfare' legislation, such as Bismarck's in Germany, or that developed in the Nordic countries in the 1890s. It is significant that the application of the sample survey method (then called 'representative' survey) was first tested in Norway in 1895, precisely in view of preparing a new law enacting general pension funds and invalidity insurance: this suggests the consistency of the political, technical, and cognitive dimensions of this co-construction.

These forms of consistency are found in the statistics systems that were extensively developed, at a different scale, after 1945. At that time, public policies were governed by a number of issues: the regulation of the macroeconomic balance as seen through the Keynesian model, the reduction of social inequalities and the struggle against unemployment thanks to social-welfare systems, the democratization of school, etc. Some people then spoke of 'revolution' in government statistics (Duncan and Shelton 1978), and underscored its four components, which have largely shaped the present statistics systems. National accounting, a vast construction integrating a large number of statistics from different sources, was the instrument on which the macroeconomic models resulting from the Keynesian analysis were based. Sample surveys made it possible to study a much broader range of issues and to accumulate quantitative descriptions of the social world, which were unthinkable at a time when the observation techniques were limited to censuses and monographs. Statistical coordination, an apparently strictly administrative affair, was indispensable to make consistent the observations resulting from different fields. Finally, beginning in 1960, the generalization of computer data processing radically transformed the activity of bureaux of statistics.

So, 'official statistics,' placed at the junction between social studies, mathematics, and information on public policies, has become an important research component in the social studies. Given, however, that from the institutional standpoint it is generally placed outside, it is often hardly perceived by those who seek to draw up a panorama of these sciences. In fact, the way bureaus of statistics operate and are integrated into administrative and scientific contexts varies a lot from one country to another, so a history and a sociology of social studies cannot omit examining these institutions, which are often perceived as mere suppliers of data assumed to 'reflect reality,' when they are actually places where this 'reality' is instituted through co-constructed operations of social representation, public action, and statistical measurement.

Abstract

Status and roles are fundamental concepts in sociology, but have been conceptualized in a myriad of different ways. For example, do status and roles refer to a stable set of positions and expectations or do they refer to more fluid processes of interaction? The way these concepts have been defined over the years has impacted the way their relationship has been characterized. The social psychological study of the relationship between status and roles has traditionally fallen under two main camps: structural-functionalism and symbolic interaction. This article discusses differences in how the definitions of status and role have changed over time under both the functionalist and symbolic interactionist camps. Although these two lines of thought have developed under different theoretical trajectories, they actually create a complementary understanding of the relationship between status and roles. In sum, this article makes the case for the need to develop both lines of thought more fully in conjunction with one another.

Social psychological research in the relationship between status and roles has had a rich and complex history. This relationship has been complicated by the fact that the definitional content of what 'roles' and 'status' are has varied across different areas of research. Social psychological research on 'roles and status' has traditionally fallen under two major paradigmatic camps: one whose roots have structural-functionalist underpinnings and the other whose roots are embedded in symbolic interaction. In the quest to characterize the relationship between status and roles, structural-functional research and symbolic interactionist research have differentially emphasized the extent to which they conceive of roles and status as being stable sets of attributes, expectations, and behaviors versus being flexible dynamic processes.

On the one hand, the structural-functionalist camp has over the years viewed the development of intragroup status hierarchies as a process, which in turn impacts and is impacted by the extent to which actors take on stable role expectations. These expected behaviors act as an extension of individuals' position within a group's status hierarchy. On the other hand, the symbolic interactionist camp has tended to view the development of role behaviors as a shared social process, which impacts and is impacted by the extent to which interactants hold or aspire to hold certain stable status positions. As a result, these two lines of research conceptualize the interplay between status and roles differently and focus on different social outcomes. The structural-functionalist camp has tended to be more concerned with the development of patterned intragroup interactions, such as the process of role differentiation and the creation of ingroup status hierarchies, while the symbolic interactionist camp has tended to be more concerned with the development of inter- and intrapersonal interactions, such as the processes of role creation and the maintenance of one's self-identity. Given that the two major paradigms have differing conceptualizations of the definitions of 'roles' and 'status,' this article will discuss the interplay of status and roles along the way their definitions have traditionally developed within both the structural-functionalist and symbolic interactionist paradigms.

Structural-Functionalism

'Status' as a Social Position and 'Roles' as Associated Behavioral Expectations

In early structural-functionalist works, 'status' was not always considered a dynamic process, but instead referred more to stable societal positions, which were associated with certain 'roles,' or normative behaviors. In his book, *The Study of Man*, anthropologist Ralph Linton has famously been credited for being the first to define 'status' as a societal position imbued with certain normative privileges and responsibilities, where status is a "… a position in particular pattern" (1936: p. 113), which "… is simply a collection of rights and duties" (1936: p. 113). For Linton, roles referred to the behaviors associated with enacting or embodying one's status or position in society: "A role represents the dynamic aspect of a status…. When he puts the rights and duties which constitute the status into effect, he is performing a role" (1936: p. 114).

Linton divided statuses into two types. For Linton, status positions could either be ascribed or achieved, a distinction that is still utilized to this day. Ascribed statuses are social positions that are accorded to an individual without reference to the individual possessing any special personal talents or skills, such as those assigned to individuals based on their age or gender, while achieved statuses are those social positions that individuals can attain competitively through skill and effort. However, according to Linton (1936), most statuses in society are ascribed. Even those statuses that are supposedly achieved are in actuality frequently circumscribed because the opportunities to attain many achieved statuses are likely to be limited by individuals' ascribed statuses. For example, even if they are equally skilled at academics, not all individuals have the equal opportunity to become a college student. Other factors, such as family income, can limit many students.

Linton's idea of status and roles as inseparable building blocks around which society is built is representative of the early structural-functionalist view that status and roles are fundamentally important to the successful workings of society. Since functionalists conceptualize society as being built upon

patterned reciprocal interdependencies among people, this highlights the importance of statuses as positions and roles as behaviors that create and maintain the social interdependencies around which society functions in order to survive. As Linton stated: "[S]ocial systems serve as guide to the shaping of individuals and their arrangement in certain relations to each other, this combination of shaping and arrangement making it possible for the mutually adjusted individuals to function together as a society," (1936: p. 107) for "Status and role serve to reduce the ideal patterns for social life to individual terms. They become models for organizing the attitudes and behavior of the individuals so that these will be congruous with those of the other individuals participating in the expression of the pattern" (1936: p. 114). In other words, carrying out expected roles or behaviors associated with certain social positions is what helps maintain the social order of interdependent relationships that undergird society.

Talcott Parsons (1951), one of the originators of modern functionalist theory, also took roles and status as fundamental building blocks of social life in describing the social system. For Parsons, 'the status–role' is fundamental for individual participation in social life because positional status always places individuals in relation with one another. It was this relational aspect of status as positions that determined interaction between individuals through associated role behavior: "…[P]articipation has two principle aspects. On the one hand there is the positional aspect-that of where the actor in question is 'located' in the social system relative to other actors. This is what we will call his status, which is his place in the relationship system considered as a structure, that is a patterned system of parts. On the other hand there is the processual aspect, that of what the actor does in his relations with others seen in the context of its functional significance for the social system. It is this which we shall call his role" (Parsons, 1951: p. 25). Along this focus on the relational aspects of different status positions, Robert K. Merton extended the original conception of having one role associated with each status position, to the idea of a role set, where "each social status involves not a single associated role, but an array of roles" (1957: p. 110). A role set is a series of different behaviors associated with a single status position. Individual actors in a specific status position will play different roles depending on the status positions of the others they are interacting with. By invoking the idea of a 'role set,' Merton focused researchers' attention onto the plethora of role relationships associated with holding a certain status position. After all, the expected behavior of a role occupant differs depending on the social position of the 'other' they are interacting with. For example, the status of a police officer would invoke different role expectations for behavior depending on if the officer was interacting with a potential criminal, a victim, the press, his or her colleagues, or his or her superior.

Under Parsons and Merton's direction, functional role theory focused on understanding (1) how stable social relations could invoke role behavior from status inhabitants and (2) how social structure can shape role relations in ways that impact individuals' ability to carry out different roles. Since all individuals hold several different social positions associated with different roles, they are subject to tensions that arise from inconsistent and incompatible role expectations. All individuals face differing degrees of role congruency (Sarbin and Allen, 1968), or compatibility, among their different roles or in their different expectations for a single role. In turn, these inconsistencies subject individuals to varying degrees of role conflict and role strain (Goode, 1960). Role conflict is produced when an individual holds different statuses that produce incompatible role expectations, such as the tensions that might arise when an individual is faced with the dilemma of whether to work overtime as he or she tries to fulfill both the role of devoted parent and loyal employee. Role strain is created when an individual experiences difficulty in carrying out their role obligations, such as when the expectations of the different roles associated with a particular status position conflict. For example, parents often experience role strain when buying presents for their children. On the one hand, the parent role entails the expectation of making sound financial decisions that fit under the family's budget, but on the other hand, the parent role also entails trying to provide their children happiness by giving them things they may want.

'Status' as Social Prestige and 'Role Differentiation'

Another path by which early structural-functionalists considered the relationship between 'status' and 'roles' was in examination of the processes by which individuals in task-oriented groups attain social positions high in status or social prestige. Under this line of research, the term 'status' took on extra meaning besides referring to status as a social position. Although Linton is often credited for propounding a definition of status as a stable social position, he actually mentioned the duality of status both as a social position, and as the social honor or prestige derived across the aggregate of one's different social positions: "*the status* of any individual means the sum total of all the statuses which he occupies. It represents his position with relation to the total society" (italics in original, p. 113). Similarly, in this line of work, the definition of status is more similar to Max Weber's 'status,' which refers to the degree of honor, social prestige, or respect accorded to an individual by others based on one's social position (1964[1947]).

Delving into status as positions that are due deference or respect led to work focused on the process of role differentiation between members of a group. In particular, Robert Freed Bales and colleagues in their group laboratory experiments at Harvard noticed the tendency of small task-oriented groups to parse group members into differentiated role positions over time even when the groups were essentially homogenous and without a preexisting status order to begin with. What Bales and colleagues noticed was the development of consistent patterns in the extent to which group members came to a consensus around who in the group (1) provided quality ideas toward solving the group task, (2) guided the group forward on the group task, and (3) was well liked or popular. They also noted that members' ratings of group members correlated with group members' actual behaviors in interaction. The interaction process analysis method developed by Bales (1950) allowed researchers to categorize group members' behaviors along 12 different interactive behaviors (shows solidarity, shows antagonism, shows tension release, shows tension, shows agreement, shows disagreement, gives suggestions, asks for suggestions, gives opinion, asks for opinion, gives information, and asks for information). This allowed

researchers to rank group members along different criteria: (1) who talked the most, (2) who received the most interaction, (3) who provided the best ideas on the group task, (4) who was most effective at guiding the group forward, and (5) who was the most liked. What the laboratory study patterns suggested was the emergence of different functional leadership roles into two complementary types of leaders: an instrumental task leader and a socioemotional leader.

On the one hand, the instrumental task leader is a position where other group members highly rate the occupant as the most competent or skilled group member on the group task, but who is not well liked by others. On the other hand, the socioemotional leader is a position where the occupant is highly liked by others, but who is not the most highly rated on competence at the group activity. What Bales and colleagues found was that evaluations of these different group leaders mapped onto the actual role behavior of group members (Bales, 1958; Bales and Slater, 1955; Slater, 1955). Task leaders were more likely to not only contribute problem-solving ideas and receive the most agreement, but also exhibit more antagonism. Socioemotional leaders were more likely to initiate positive reactions to others, receive more solidarity and tension release. As a result, the roles of these different leaders became differentiated, such that task leaders pushed the group forward with regard to focusing attention on the instrumental task at hand, while socioemotional leaders kept the group together by focusing attention on solving intragroup tensions.

According to work in this field, the emergence of role differentiation, particularly with respect to leaders, helped maintain a group's survival – this was because they conceived of task contributions in a zero-sum way such that the more one individual engages in task acts, the more he or she limits others' opportunities for doing so. This line of research was interested in how role differentiation enhanced the positive functioning of the group as different specialists catered their role behaviors to solve different needs of the group. For example, having a task leader helped the group fulfill the need to coordinate task activity toward successful achievement, while having a socioemotional leader fulfilled the need to promote positive integrative feelings and relations within the group that might deteriorate while engaging in conflict around task-oriented activities. Research on the differentiation between leadership roles fell off by the 1970s, as researchers realized these processes were not universal and that the situations under which role differentiation occurred were limited. For example, Burke (1967, 1968, 1971) found that role differentiation into separate roles for task and socioemotional leaders was less likely to occur when group members accept the task activity as legitimate, such that group members are more incentivized to engage in the task and are asked to achieve consensus. Under these conditions, the instrumental task leader becomes more likely to engage in socioemotional activity and is more liked, which lessens the need and the opportunity for a socioemotional leader to arise.

'Status' as a Social Process and 'Roles' as Stable Expectations

Bales' findings spawned another very productive line of contemporary structural-functionalist research regarding the process of status differentiation. Interested in explaining the process by which stable hierarchies could emerge even in nondifferentiated groups, such that some group members come to hold more influence over group decision making and respect than others, Joseph Berger and colleagues created expectation states theory (Berger et al., 1972). The development of this new theoretical research program led the structural-functionalist line of research to move from conceptualizing status as set positions per se, and conceive status to be more of a process where some individuals achieve more influence over others in small group interaction. Under expectation states theory, members of task-oriented groups become differentiated as the group develops consensual expectations regarding which group members are more skilled or competent at the collective task. Those whose contributions are expected to be more beneficial for helping the group achieve their goal are accorded more influence in the group, such that others in the group are more likely to defer decisions to group members who are expected to be skilled at the group task. More recent work has also found that influence or status is provided to those who are perceived to be more group oriented and willing to sacrifice personal gain for the group (Hardy and Van Vugt, 2006; Ridgeway, 1982; Willer, 2009). Not only are these 'high status' group members more likely to be given more opportunity to state their opinions and have their opinions evaluated highly and validated by other group members, but also they take on the behaviors of a leader, such that they are more likely to interrupt, disagree, or emit behaviors to guide the group along. The opposite is true for lower status group members, who become less likely to state their opinions and more likely to concede to the suggestion of others. Thus, under expectation states theory, roles become relegated to being stable set of complementary expectations of the skills and behaviors attributed to those accorded different positions along an intragroup status hierarchy. Under expectation states theory, expectations, or roles produce status or intragroup influence, which in turn gives rise and legitimacy to differentiated status positions.

This view of status as a dynamic process with roles as static differing expectations attached to different status positions continues to hold even among several theoretical offshoots of expectations states theory like status characteristics theory (Berger et al., 1972) and status construction theory (Ridgeway, 2001, 2006). Status characteristics theory explains how salient status characteristics, such as gender, race, or class, become stable bases of hierarchical status inequality in groups. Status construction theory focuses on explaining the development and spread of status beliefs in society. Recent work on the social psychology of status has focused on functional importance of status hierarchies in creating differential role expectations between high and low status group members. It has been found that people respond positively when they form working relationships with others who complement them in terms of dominance, such that 'dominance complementarity' has also led to higher levels of group cohesion (Tiedens and Fragale, 2003; Tiedens et al., 2007). Indeed, Ridgeway and Johnson (1990) found that frustration and negative emotional behaviors are more likely to be engaged in when groups are unable to come to agreement on a status order. They state: "Status struggles emerge out of task-based disagreements when the

disagreeing members do not mutually agree on a resolution after an initial statement of arguments. This may … happen when two members disagree about their relative performance expectations or have nearly equal performance expectations" (p. 1203).

In recent years, work on social status and its impact on role expectations has proliferated greatly. However, an underlining theme across much recent research highlights the idea that as people are differentiated into varying status positions, the characteristics, behaviors, and even emotions attributed to these status-differentiated individuals differ in predictable ways. For example, Tiedens et al. (2000) found that high- and low-status members of groups were expected to have different emotional reactions to positive and negative group outcomes. High-status actors were expected to feel angrier when group outcomes were negative and more pride when group outcomes were positive, while lower status actors were expected to feel more sad and guilty when the group failed and more appreciation and gratitude when the group was successful. Work on the stereotype content model (Fiske et al., 1999; Fiske et al., 2002; Glick and Fiske, 2001) has found that stereotypes associated with high status groups often assume members of these groups are highly competent. Even more interesting has been their finding that many stereotypes hold an inverse relationship between perceptions of competence and perceptions of warmth of different social groups, such that many groups that hold high societal social status, but whose positions threaten status quo, are considered competent, but not warm (e.g., business women or rich people). Indeed, work on real-world status differences has found that those who hold higher social positions, such as those with more resources, are less likely to act in prosocial manner (Piff et al., 2010), more likely to violate norms of ethical behavior to achieve desired personal ends (Piff et al., 2012), and less likely to attribute social and personal outcomes with contextual explanations (Kraus et al., 2009).

To summarize, early structural-functional role theorists were interested in understanding how occupants of different social statuses learned to internalize, conform, and juggle the existing agreed-upon role expectations that their status positions subject them to. Over time, structural-functional research in roles and status moved toward a more dynamic picture of the process of both role and status differentiation. However, this move toward a more dynamic look at the differentiation processes between those of differing positions and status comes at the expense of understanding how undertaking role behavior itself can also be a dynamic process. Structural-functional explanations of role behavior tend to presuppose static normatively shared consensuses around the boundaries and expectations of a role and they also tend to assume that individuals engage in differential role behavior due to individual internalization of normative role expectations. The areas in which both early and contemporary functional role theorists are not strong in explaining include understanding role-based interactions, in particular: (1) how variety and change in the enactment of role behaviors can occur and (2) understanding how individuals resolve conflicting motivations when enacting or rejecting role expectations.

Symbolic Interactionism

'Roles' as a Process and 'Status' as Stable Extensions of Position

The symbolic interactionist approach to understanding the relationship of roles and status complements the structural-functionalist approach. While structural-functionalists have concentrated on explaining (1) how individual behaviors fall into line by following stable role expectations based around structural social inequalities and (2) how conflicting role expectations can be adjudicated by changes in the larger social structure, symbolic interactionists have reacted against this oversocialized view of individuals who unquestioningly take on and carry out expected role behaviors. Instead, the symbolic interactionist approach to the relationship between role and status allows individual identity and motivations to play a large part in carrying out role behaviors. Under symbolic interaction, the connection between individual identity and social interaction is of utmost importance in the creation of shared social meanings behind different social roles. This is because social identities help individuals frame and interpret the social situation and their place in the scenes they find themselves in. Furthermore, roles link individuals to society because each individual holds a role repertoire, which contains all the different role sets of the individual, and as such individuals' identities are a reflection of the larger society under which the individual lives and functions.

George Herbert Mead's conception of the role forms the basis around which symbolic interactionist research regarding the relationship between roles and status are founded (1934). For Mead, 'taking the role of the other' is essential to social interaction. To take on the role of the other, one must be able to view the world (including oneself and one's behaviors) through the standpoint of others. Taking on the role of the other is important because it is only through being able to view how others might see one and one's actions that an individual is able to adjust his/her actions to fulfill his/her roles. As Mead stated: "It is through taking this role of the other that he is able to come back on himself and so direct his own process of communication…. The immediate effect of such role-taking lies in the control which the individual is able to exercise over his own response" (1934: p. 254). Further, according to Mead, it is only through taking the role of the 'generalized other,' such that one can see oneself through the eyes of society or all others who may hold related positions, that one will come to know oneself.

This conception of identities as a lens to the world works when one assumes that social identities are attached to relatively stable status positions. When one assumes that the underlying identity attached to a status position is stable, it allows for individual agency in the interpretation and performance of the role expectations attached to those stable status positions. Each individual has the capacity to make the role identity their own and will use that role behavior to try to draw others into their own definition and interpretation of the interaction. As such, the symbolic interactionist approach to roles and status moves the focus of research away from trying to understand how social structural positions impact individual behavior, and instead concentrates attention on how individuals may affect and change the behavior of others in interaction

by the way they play the role attached to their situationally salient role identity. The explanation for why individuals perform role behavior differs between structural-functionalists and symbolic interactionists. For structural-functionalists, because individuals occupy certain social positions, they conform or are expected to conform to the role behaviors associated with their social positions. For symbolic interactionists, individuals carry out the actions they do because they are trying to frame or uphold a certain identity in the eyes of others. As a result, individuals will use their behaviors to try to shape the way others interpret and define the situation. As such, role behavior becomes the means by which individuals negotiate the creation of shared meanings with others in interaction.

The enactment of roles as a performance was propounded very early on in Erving Goffman's (1959) work on impression management. A founder of the dramaturgical school of symbolic interactionism, Goffman discusses social interaction and the development of the self as a performative experience, where the setting and roles provide individuals scripts by which they can engage with one another. Individuals attempt to achieve their aims through the way they perform the role identities that they take on. In his work, Goffman articulated the importance of role performance while inhabiting a particular social position or identity: "A status, a position, a social place is not a material thing, to be possessed and then displayed; it is a pattern of appropriate conduct, coherent, embellished, and well articulated. Performed with ease or clumsiness, awareness or not, guilt or good faith, it is none the less something that must be enacted and portrayed, something that must be realized" (1959: p. 75). Under impression management, Goffman suggested that people tailor their behavior to try to produce the view of themselves that they want others to see. In other words, individuals use role performance to shape others' impressions of themselves for "Regardless of the particular objective which the individual has in mind and of his motive for having this objective, it will be in his interest to control the conduct of others, especially their responsive treatment of him. This control is achieved by influencing the definition of the situation which others come to formulate, and he can influence this definition by expressing himself in such a way as to give them the kind of impression that will lead them to act voluntarily in accordance with his own plans" (Goffman, 1959: pp. 3–4). As such, Goffman's work highlights how individuals can instrumentally use role behavior to dynamically affect how others view their social position in interaction.

Ralph Turner further shifted symbolic interactionists' attention away from 'role taking' to one of 'role making' (1975 [1962]). By proposing researchers focus on how individuals create shared meanings for roles, Turner emphasized the importance of individual agency in the creation of role behavior. According to Turner, the way that people perform roles differs and that much of role behavior is not predetermined by shared normative expectations before interaction occurs, but instead arises in each interaction. Under symbolic interaction, consensus, and the negotiation of shared meanings is the goal of interaction, rather than a given. Turner states that: "The idea of role-taking shifts emphasis away from the simple process of enacting a prescribed role to devising a performance on the basis of an imputed other-role. The actor is not the occupant of a position for which there is a neat set of rules … but a person who must act in the perspective supplied in part by his relationship to others whose actions reflect roles that he must identify," (Turner, 1975[1962]: p. 111). Variation in role-behavior stems not only from individual agency, but also because the content of roles can be ambiguous themselves: "Roles 'exist' in varying degrees of concreteness and constancy, while the individual confidently frames his behavior as if they had unequivocal existence and clarity. The result is that in attempting from time to time to make aspects of the roles explicit he is creating and modifying roles as well as merely bringing them to light; the process is not only role-taking but role-making" (Turner, 1975[1962]: p. 110).

For Turner, the actual enactment of a role is shaped not by the specific actions an individual undertakes in carrying out the role, but more in the 'mind-set' an individual associates with the role. Turner argued that, "The individual acts as if he were expressing some role through his behavior and may assign a higher degree of reality to the assumed role than to his specific actions. The role becomes the point of reference for placing interpretations on specific actions, for anticipating that one line of action will follow upon another, and for making evaluations of individual action" (1975[1962]: p. 111). Depending on which role out of one's role repertoire is being engaged in, individuals create and adjust their definitions of a situation. Turner's work highlights an inherent tension between one's self-identity and the enactment of one's role identities. On the one hand, an individual's conception of his/her self is an entity that is beyond all the different roles they have in their role repertoire and this aspect of the self colors how the individual engages in any one of his/her roles. On the other hand, a person's self is also linked to the roles that the individual often engages in, such that one's self-concept is tied to "… those roles that are still played when not called for and color the way in which other roles are played" (Turner, 1978: p. 2).

Turner also created the idea of a role–person merger to describe the occurrence when a role becomes so salient to the individual that the role becomes integrated into their personal behavior. A role–person merger occurs when people become too attached to a role leaving them unable to dissociate from or compartmentalize that role even when it may be to their benefit to take on an alternative role. This can create role conflict for individuals, as "Many of the discrepancies between role prescription and role behavior … can be explained by the individual's inability to shed roles that are grounded in other settings and other stages of the life cycle" (Turner, 1978: p. 1).

However, as much as people come to embrace their roles, they also leave them. The concept of role distance was created by Goffman (1975[1961]) to account for the process by which individuals disassociate themselves from certain roles. Sometimes, role distance comes from people transitioning out of roles, such as when a grade-schooler refuses to hold hands with parents because it is a sign of being 'babyish.' At other times, role distance comes from a disinclination to fully embrace a role, for example, when teens are unwilling to be seen as 'dependents' of their parents. It is interesting to note that

many examples of this type of role distance can be found when an individual is struggling with accepting the (usually low) status of the position they are holding, such as when a working parent loses their job and becomes a 'stay-at-home' parent. As Goffman himself notes: "Situated roles that place an individual in an occupational setting he feels is beneath him are bound to give rise to much role distance…. Some of the most appealing data on role distance come from situations where a subordinate must take orders or suggestions and must go along with the situation as defined by superordinates" (1975[1961]: p. 128).

If people's self-identities are bound to a set of role identities (Burke, 2004; Burke and Reitzes, 1981), this begs the question of how do different roles come to gain or lose importance, such that it is possible for an individual to have a role–person merger or engage in the process of role distance? Identity salience refers to the probability that a certain role identity will be enacted (Stryker, 1968). According to Sheldon Stryker (1968), all the identities in an individual's role repertoire are rank ordered in a salience hierarchy. The higher a role identity is in the salience hierarchy, the more likely it is that the individual will enact and utilize that role across different social situations. According to Stryker's identity theory (1968), a role identity will be more salient the higher his/her commitment to that identity. Commitment to a role heightens the more an individual believes that occupying a certain role is essential in maintaining important social relationships. Therefore, commitment to a role for an individual is essentially based on two main factors – the number of relationships that depend on the individual fulfilling a certain role and the extent to which the individual values each of those relationships.

Symbolic interactionist work brings insight into how roles connect the individual self to larger society. First, roles are central to conceptions of self-concepts because ideas of the self are composed of different role identities (McCall and Simmons, 1966; Stryker, 1968). Second, each individual's 'self' as a ranked hierarchy of role identities is actually a reflection of an individual's place in society, and a mirror image of the network of social relationships that comprise society itself (Stryker and Macke, 1978). Recent work on the enactment of roles, in particular research in identity control theory on self-verification, focuses more on how internal processes impact how individuals choose to engage and carry out their roles (Burke, 1991, 2006; Burke and Cast, 1997). This type of work focuses on understanding how individuals may change their behaviors when others' reflected meanings do not match the identity standard they want to achieve. In other words, individuals' behaviors are important because they produce meanings that support and maintain individuals' self-meanings in interaction. In this line of research, leaders do not engage in leadership behaviors just because they are rising or fulfilling expectations of others for how leaders should behave. Rather, their actions stem from a motivation to control perceptions of others to make others' reactions conform to what the actors themselves believe is fitting for their role. In other words, leaders engage in behavior to try to elicit others' actions to match their identity standard of what reactions are due to a leader in a given situation. When individuals perceive that their actions are being interpreted as fulfilling the identity they want to achieve, they are not likely to change their behaviors. However, when they feel that their identity is being perceived differently than the ideal they would like to attain, this dissonance is grounds for behavioral change. This type of path can shed light on what the behaviors individuals may engage in when they are not accorded the proper amount of esteem or respect they believe they are entitled to. Work in this vein has also found that the more an individual has personal, interpersonal, and structural resources, the higher their ability to self-verify their own personal and role identities (Cast, 2003; Stets and Cast, 2007). This creates the potential for a reinforcing feedback pattern that higher status individuals are more able to take control of situational meanings, since the more an individual is able to self-verify the more resources he/she gains from interaction that can be used toward future identity verification.

Summary

Social psychological work on the relationship between roles and status not only has had a long and rich history, but also continues to thrive. Although work on the relationship between roles and status is often characterized as falling into two oppositional camps, it is clear that the functionalist and the symbolic interactionist approaches also complement one another in their understandings of how social status affects social roles and vice versa. Contemporary structural-functional approach has moved away from considering social status as static and currently focuses on the process of status differentiation and its impact on subsequent role expectations (Rashotte and Webster, 2005; Ridgeway, 2006). There has also been large growth in structural-functional research examining the impact of status hierarchies, status position, and status strivings on people's expectations and enactment of role behaviors (Anderson and Kilduff, 2009; Anderson et al., 2012a,b; Bendersky and Hays, 2012). However, the structural functionalist perspective is still weak at explaining the wide variation in how certain behaviors come to gain shared meaning or describing the processes by which individuals choose to engage in the roles that they do. On the other hand, the symbolic interactionist approach focuses heavily on enactment of role expectations as a process. Both traditional and contemporary symbolic interactionist research has emphasized individual agency in engaging in role behavior. Current work has delved even deeper into the factors that impact the process by which individuals engage in different role behaviors in the process of identity verification and has closely examined how resources, including those that stem from different social positions can impact individuals' ability to successfully achieve their desired identities by manipulating perceptions created in interaction (Cast, 2003; Stets and Cast, 2007; Burke, 2006). However, unlike structural-functional work on the emergence and outcomes that result from the creation of status hierarchies, the symbolic interactionist approach is not strong in explaining how such inequalities between resources and status positions may arise in the first place. In all, research in both traditions complement each other highly. As work continues to progress along both paradigms, it seems quite promising that these

paradigms' differing definitions and emphasis on roles and status will develop an even fuller picture of complex relationship among all the different social psychological processes that connect roles to status and back again.

Status and Role: Structural Aspects

John Scott, University of Copenhagen, Copenhagen, Denmark

Abstract

This article reviews the development of the concepts of status (position) and role within anthropology and sociology, showing how a specific form of role theory was elaborated within structural functionalism. Critical perspectives and elaborations are reviewed, and it is shown that the concepts have a continuing relevance within a variety of theoretical perspectives.

This article examines the development of concepts of status (social position) and role in social anthropology and sociology, tracing their development into mainstream concepts and into the development of role theory. It also explores the criticisms leveled against these structural ideas from symbolic interactionist and from ethnomethodological points of view. It is suggested that these criticisms have, in fact, broadened the structural focus and provide a number of important complementary ideas.

The closely connected concepts of 'status' and 'role' have a long and complex history in a number of different traditions of social thought, but their contemporary meanings were developed largely during the first half of the twentieth century. Despite it having been Shakespeare who claimed that 'all the world's a stage,' it was the social psychologists of the early twentieth century who systematically employed the concept of role and so paved the way for later 'dramaturgical' approaches to social life. This work also prepared the way for those who developed the idea of status as the structural position corresponding to a role. The term status, however, has been used in two quite different ways, only one of which is directly relevant to this discussion. One usage has referred to hierarchical differences of prestige and social honor in systems of social stratification (see Social Stratification); the other has referred, more generally, to any structural position or location in a social system. It is the second sense that will be discussed in this article.

Status as Structural Position

The hierarchical concept of status was popularized by Max Weber, who contrasted stratification by status with stratification by class (Scott, 1996). In the 1930s, however, cultural anthropologists used the word status when referring more generally to positions or locations in a social structure, regardless of whether these involved any ranking by prestige (Linton, 1936). This usage was adopted rapidly by structural-functionalist sociologists. Although this led initially to some confusion about whether or not particular 'statuses' were hierarchically ranked, the new usage soon became established (Parsons, 1942b). Some investigators resolved this confusion by using the words 'position' or 'location' in preference to status (Warner, 1952: 46), and this unambiguous terminology is adopted in this article and is recommended for wider use.

The idea of status as structural position originated in the conceptualization of social structure as comprising culturally defined institutions. This had its origins in the sociology of Durkheim, but it was the development of a clear and systematic understanding of culture by American anthropologists (Kroeber, 1917; White, 1949; see Kluckhohn, 1954) that gave the idea its contemporary form. The culture of a society was seen as defining a set of standardized normative patterns that people are expected to follow in their social actions (Parsons, 1951). These social institutions regulate individual and group behavior by defining the nature of their social relations with each other. Institutions define "proper, legitimate or expected modes of action or of social relationship" (Parsons, 1940: 53), and so guide and channel behavior. This view of social structure as "a patterned system of social relationships of actors" (Parsons, 1945: 230) rapidly became a central concept in sociological analysis.

The institutionalized expectations that people share define their social positions in relation to other positions and specify their expectations in relation to the anticipated actions of the individuals who occupy these other positions (Parsons, 1942b: 143). The knowledge that people have about social positions provides them with conceptual maps that they can use to organize their social actions. This knowledge, of course, is contained in individual minds. Such *shared* knowledge, however, involves a reciprocity of expectations among actors, who sanction each other's behavior through their reactions to any deviance from the expectations. People do not simply 'know' the social positions that make up their society, they experience social pressure to conform to the expectations they involve. This solidifies expectations as institutionalized collective representations (Davis, 1948: 87), and social positions, then, are to be seen as Durkheimian social facts that constrain the behavior of individuals.

The behavioral expectations associated with a position define the role that their occupants are to play. Roles are definitions of what people are expected to do in different situations. Roles include the specific rights and obligations entailed in a social position (Dahrendorf, 1958: 36). They tell us what to do and what to expect others to do (Parsons, 1940: 54). They provide us with a definition of the situation that defines the goals, the means, and the attitudes that are recognized culturally as legitimate for those who occupy particular social positions and sets the limits within which they may legitimately act (Williams, 1960).

Some writers have used the concept of role to describe the *actual* behavior associated with a position, but most have recognized that a normative focus requires a concern for

expected behavior (Levy, 1952: 158–160). The relationship between expected behavior and actual behavior is complex and involves multiple determinants, so there is rarely a one-to-one correspondence between norms and behavior. The fully institutionalized social relation, in which there is a complete consensus and perfect conformity allows us to analyze one set of determinants among the many affecting other people's behavior (Parsons, 1951: 39).

These ideas were taken up during the 1950s as the basis of a 'role theory' that set out a comprehensive paradigm for role analysis. The most influential formulation of this was that of Gross et al. (1958), who used it to explore the behavior of school superintendents. They did this using Merton's (1957) argument that each social position is associated with an array of role-specific forms of behavior that together make up a 'role set.' A medical student, for example, must act as a student not only in relation to other students, but also in relation to teachers, doctors, nurses, social workers, patients, medical technicians, and so on. In each of these relations, the student is likely to encounter different expectations about her or his behavior (Merton, 1957: 112). Gross et al. (1958) showed that the school superintendent must negotiate the conflicting expectations held by teachers, parents, children, governors, and ancillary staff. It was recognized that this definition of role expectations is likely to produce varying degrees of strain or conflict in role expectations. Occupants of different positions may legitimately expect behavior that conflicts with that expected by others, and it may be difficult for an actor to meet all expectations equally or simultaneously. They must balance one set of demands against another and resolve the resulting tensions. This idea of 'role conflict' has been central to many applications of role theory.

Socialization and Conformity

Although this work concentrated on the structural aspects of position and role, it was complemented by those who worked on a social psychology of roles (Newcomb, 1950). These writers explored the learning processes through which roles are acquired and the social pressures to conformity that exist in face-to-face situations. Socialization and conformity were central principles for role theorists, and their overemphasis has been subject to persistent criticism.

Role theorists see the norms that define social positions as being learned through a process of socialization. The expectations of others are *internalized* in the personality as it is formed. They become objects of moral commitment, and individuals are likely to be strongly attached to them. They tend to regard conformity as a duty (Parsons, 1940).

This is associated with the argument that there is consensus over social norms. Members of a society share their moral commitments and so violations are met with guilt or shame in the violator and indignation or condemnation in those whom the deviance affects. Deviance from these shared norms is likely to result in 'corrective forces' or sanctions that may vary from mild disapproval to overt coercion. For many, this led to the conclusion that deviance is both infrequent and automatically corrected. Societies were seen as self-regulating systems in which actors had little choice but to conform.

The degree of consensus in a society rarely reaches this level, however, and individuals are never perfectly socialized (Wrong, 1961). These points were raised especially forcefully against Parsons, but even he recognized that the 'completely institutionalized' social relationship was a rarity. He held that, although broad descriptive contrasts could be drawn between societies in terms of their common values, "when dynamic problems of directions and processes of change are at issue, it is essential to give specific attention to the elements of malintegration, tension and strain in the social structure" (Parsons, 1942a: 117). Nevertheless, the mainstream of role theory overemphasized both consensus and internalization. It was conflict theorists such as Dahrendorf (1958) who showed that role expectations have to be seen in relation to the distribution of power and that this can give them a solidity that does not depend on a consensus of opinion.

What passes for consensus actually may be the dominance of the ideas of a powerful group (Rex, 1961; Shils, 1961). A minority may be able to use its resources to institutionalize its own norms for the population as a whole. This may be especially effective where the majority of the population forms a relatively unorganized mass without strong counterinstitutions of its own.

Mapping Social Positions

The structural-functional approach to positions and roles identified social positions as unintended cultural patterns that form an institutional structure. This was seen as corresponding to actual social relations among occupants of the positions and hence pointed to a conception of relational structure alongside institutional structure (López and Scott, 2000). Thus, social positions could be mapped as structures of relations independent of the cultural meanings that constitute them. The earliest attempt to set out a formal model of relationally defined positions was that of Nadel (1957), who pioneered a mathematical approach that has been taken up in social network analysis by advocates of block modeling (White et al., 1976; Boorman and White, 1976). In a block model, the social relations of individuals are represented in a matrix of connections that discloses 'structurally equivalent' individuals and defines these as social positions. Although some such positions may correspond to culturally defined norms, those such as, for example, social classes may be purely *de facto* social positions. White (2008) has attempted to bring together cultural and relational points of view (see Emirbayer and Goodwin, 1994).

Other approaches to social network analysis have identified relational positions of centrality and peripherality, seeing central intermediaries as, for example, brokers in power relations (Burt, 2005). Combining these approaches with the identification of cliques and clusters in networks of relations has made it possible to identify social positions as associated with varying degrees of social capital (Lin, 2001; Burt et al., 2001). Although some of these approaches depart from the tenets of role theory, they have provided an important and powerful extension of the idea of social position.

Role-Taking and Role-Making

Structural-functional and conflict theories of position and role, supported by social psychological theories of socialization and conformity, lay at the heart of mainstream sociology from the 1940s to the 1960s. During the 1960s, however, radical and forceful objections were raised against these theories . The immediate origin of the sociological concept of role had been Mead's (1927) account of taking the role of the other, and critics of the mainstream turned to Mead for support. They questioned the cultural determinism and oversocialized image of the actor who saw people as the mere puppets of structural forces, which had been espoused in many of the simpler textbook versions of role theory that had popularized its ideas. Blumer (1962: 189) reiterated the original insight that a structure of positions is simply a 'framework inside of which action takes place.' It is a conceptual guide for action, not an external, substantial entity or an independent coercive power.

Turner (1962) took this argument to the heart of role theory. He held that the emphasis on conformity gives only a partial view of role behavior. It stresses imitation and ignores innovation, failing to recognize that role-takers are also 'role-makers': that is, individuals do not simply take over roles as templates for conformist behavior but must, of necessity, improvise. The role knowledge that individuals learn during their primary and secondary socialization cannot give them precise, programmed instructions for behavior in all of the many unique and unpredictable circumstances in which they are likely to find themselves, especially when faced by role conflict. Individuals tentatively interpret and reinterpret each other's actions in the situations that they encounter, recreating their roles from the raw materials provided to them during socialization (Turner, 1962: 23). Shared knowledge of social positions sets the general conditions for action, but it does not fully determine it (Blumer, 1962: 190). The normative functionalist approach to role-taking has to be broadened into a more comprehensive account.

The fullest development of this view was that of Erving Goffman (1959, 1963), who explored the ways in which individuals actively and creatively construct the images that they present in their role behavior. Goffman systematically employed the theatrical metaphor of role-playing, holding that individuals are never merely actors following a script, but are authors as well. Using such ideas as props, scenery, front stage, and back stage, Goffman showed how public performances depend on the more private situations to which individuals can withdraw. He introduced a number of novel concepts, most notably 'role distance' to describe the psychological distancing that actors may establish from the role expectations that they find uncomfortable or uncongenial.

A Sense of Social Structure

The criticisms made from symbolic interactionism added a whole new dimension to the analysis of position and role. Although some critics of mainstream views saw this as a complete alternative to the orthodoxy, others saw it as complementing the structural account. These differences persist and have been compounded by a more radical line of argument from phenomenology and ethnomethodology. Aaron Cicourel has produced the most systematic statement of this critique.

Cicourel asked the fundamental question: How is role-taking possible? His answer was that the taking and making of roles rests on a set of cognitive processes through which actors give meaning to the world and so sustain a 'sense of social structure' (Cicourel, 1972: 11). People do carry role information in their heads, but they also must be able to recognize when one particular position or role is relevant, and they must be able to infer what expectations others have of their behavior. They cannot make sense of their social world simply by drawing on the role and positional knowledge that they have learned during their socialization. Before they can apply norms in particular situations, they must arrive at an understanding of what kind of situation it is. This means that "members of a society must acquire the competence to assign meaning to their environment so that surface rules and their articulation with particular cases can be made" (Cicourel, 1968: 52). This ability to infer and to impute meaning to situations is a practical skill that is an essential condition for any social life at all. Cicourel saw this skill as an interactional competence, making explicit parallels with Chomsky's concept of linguistic competence. Although he did not adopt Chomsky's own rationalist theory of the mind, Cicourel did take over his stress on the generative capacities that are provided by human competences. It is their practical, meaning-making skills that allow people to use their knowledge of social norms to generate appropriate role behavior. The structural aspects of positions and roles, therefore, were seen by Cicourel as resting on the possession of a complex set of cognitive procedures (also termed inductive, interpretive, or inference procedures) that operate in the same way as the deep structure grammatical rules of a language.

Cicourel illustrated these cognitive procedures by drawing on Alfred Schutz's discussion of the assumptions that people must make for social interaction to be possible. Schutz held that individuals must assume a reciprocity of perspectives between themselves and their potential partners, they must fill in the gaps in their knowledge through the *et cetera* principle, and they must assume that things occur as 'normal form.' These and similar cognitive procedures constitute the mental module that makes it possible for actors to generate appropriate but innovative responses in changing circumstances, despite the fact that they have only fragmentary and uncertain evidence available to them. They allow people to assign meaning and relevance to the objects in their environment and to construct definitions of the situation that allow them to infer which of the norms stored in their memories are relevant. People build a sense of social structure that allows them to orient themselves appropriately in the various situations that they encounter. Once the meaning of a situation has been decided, norms can be invoked on the assumption that there is a consensus among those with whom they interact and that these are, indeed, the appropriate norms. Normative order and role behavior, therefore, are negotiated and constructed on the basis of the underlying sense of social structure that interactional competence makes possible.

Gender and Sex Roles

Liberal feminist work on sex roles was one of the earliest applications of the Parsonian view of role, but it is in wider feminist approaches that novel ideas also have developed. Betty

Friedan (1962) took up Margaret Mead's (1950) earlier work to set out a view of socialization into culturally defined gender roles corresponding to biological sex differences (see also Oakley, 1972). The ways in which boys learn the norms of masculinity and girls learn those of femininity involve unconscious learning through interactions with their parents and others, through their play with specific types of toys, and in their games with other children. Nancy Chodorow (1978) applied a psychological perspective to this process of gender socialization. This differentiation of roles is reinforced in adult; life through a differential participation in employment and public life and the overall structure of gender positions has been seen as constituting a structure of patriarchy (Walby, 1997). These arguments on the nature of gender positions and roles have been extended into wider issues of sexuality and sexual orientation through discussions of norms of masculinity and the formation of gay, lesbian, bisexual, and transgendered identities (Connell, 1997; Weeks, 2000).

Judith Butler (1990) took a poststructuralist approach to these issues and provided a novel extension of Goffman's ideas through her work on performativity. Gender differences, she has argued, result from performances that represent idealized gender norms. Masculinity and femininity, therefore, are the results of repeated actions that create the appearance of fixed biological differences. Drawing on Foucault's (1961, 1975) work on practices of surveillance, discipline, and self-control, she saw these performances as discursive constructions that regulate subjectivity and identity.

Conclusion

Status – or position – and role remain central concepts in accounts of social structure (see Biddle, 1986). They do not tell us everything that we need to know about social structure (Lockwood, 1956, 1964), but they are essential elements in any structural account. The use of these normative concepts, however, must incorporate an awareness of the creative and innovative role-making activities that are integral to all role behavior. Role behavior is deeply implicated in the dispersed practices of surveillance and control through which actions are organized. Improvisation and negotiation are essential features of the construction of social action; however, these processes are possible only because individuals possess certain cognitive skills that allow them to infer the meaning of social situations and to build a sense of the social structures in which they must act. Structural positions and roles are human accomplishments, but they have real consequences for the people who occupy them.

Stem Cell Research and Cloning

Catherine Waldby, The University of Sydney, Sydney, NSW, Australia

Abstract

In the 1990s, human embryonic stem cell research and mammalian cloning emerged as two of the most controversial areas of biomedical research, provoking complex social responses and contestations over the status of the embryo, the reproductive rights and obligations of women, the entitlements of patient groups and aging populations, and the commercialization of reproductive biology. These developments placed unprecedented levels of pressure on governments to formulate regulations that are able to reconcile competing ethical concerns while also facilitating scientific innovation and the production of therapies to treat the medical conditions associated with disability and aging. This article will consider the ways that various social science disciplines, particularly science and technology studies and medical sociology, have responded to this situation.

Introduction

In the late 1990s, human embryonic stem cell (hESC) research and mammalian cloning emerged as two of the most controversial and promising areas of biomedical research, provoking both intense scientific interest and complex social responses. Both techniques emerged from advances made in human and animal reproductive sciences and *in vitro* fertilization (IVF) throughout the twentieth century (Clarke, 1998) but particularly since the 1980s (Edwards, 2001). A particular category of stem cell is hESCs, a term used to describe undifferentiated cells that can renew themselves and also give rise to one or more specialized cell types with specific functions in the body. Stem cells are crucial to embryonic and fetal development, but they are also found in adult tissues, particularly in the bone marrow, and they are crucial agents in healing and the replenishment of some tissues. Different categories of stem cell have different qualities. The most celebrated type of stem cell is 'pluripotent', meaning that it has the capacity to develop into almost all of the body's tissue types. Other cell types may be classified as totipotent (able to produce the entire organism) and multipotent (able to differentiate into a more limited range of cell types) (Petersen and Munsie, 2012). The most viable source of pluripotent stem cell lines is human embryos. Other stem cell sources do not appear to be as flexible or active as tissue derived from embryos.

Non-human ESCs were first isolated during the 1980s, but it was not until 1998 that the first hESCs were cultured. In that year, a research team led by James Thomson at the University of Wisconsin derived hESCs from embryos donated by couples in fertility treatment. The inner cell mass was isolated from 5-day-old embryos, and the team developed five cell lines from the tissues (Thomson et al., 1998). Thomson and colleagues demonstrated that the cells could be cultured in an undifferentiated state, frozen and thawed, and then induced to differentiate into the three main groups of embryonic tissue – the ectoderm, endoderm, and mesoderm – which in turn form into the main adult cell types.

The clinical implications of this development are far reaching. If the research could be successfully developed into therapies, it might be used to treat currently intransigent degenerative conditions – spinal cord injuries, Parkinson's disease, Alzheimer's disease – by introducing regenerating tissue into appropriate sites. It might serve as an alternative to solid organ donation, either by repairing a damaged organ in the body or creating a new organ without the need for a donor. In the process it would treat two significant, twenty-first century population health problems. First, it would provide a new biomedical method to treat conditions associated with the aging of the population in the developed world, and the associated increase in health and social care budgets. It would contribute to what is now known as the 'compression of morbidity', the contraction of disabling illness to the shortest possible period prior to death, by improving treatments for chronic degenerative conditions. Second, it would address the ever-increasing gap between tissue donation levels and patient waiting lists. While rates of organ donation have increased in many developed countries over the last 10 years, the demand for organs has far outstripped supply, as more and more conditions are considered treatable through transplant.

The clinical possibilities presented by hESC research were made even more promising by their intersection with advances in mammalian cloning. After nearly a decade of research (Franklin, 2007), Ian Wilmut and other scientists at the Roslin Institute in Scotland announced the birth of Dolly the sheep in 1997, the first mammal to be conceived by somatic cell nuclear transfer (SCNT) (Wilmut et al., 1997). SCNT involves the creating an embryo not by the usual process of *in vivo* conception, fusion of egg and sperm, but through the insertion of the nucleus of a cell from an adult's tissues into an unfertilized egg. The egg has in turn had its own nucleus removed to make way for the introduced nucleus. This creates an embryo with the genome of the adult from whom the nucleus was taken. Prior to the cloning of Dolly, biologists assumed that the nuclei of adult cells had lost their ability to proliferate into other cell types. That is, once dedicated to the production of a particular cell type – muscle, blood, skin – the nuclei could not regain their embryonic pluripotency. As Wilmut and colleagues put it, "the fact that a lamb was derived from an adult cell confirms that differentiation of that cell did not involve the irreversible modification of genetic material required for development to term" (Wilmut et al., 1997: 810).

In addition to enabling whole new animals to be cloned, these techniques are thought to have potential therapeutic applications. It may be possible to use some aspects of the SCNT technique to develop embryonic stem cell lines with the

 http://dx.doi.org/10.1016/B978-0-08-097086-8.85060-6

genetic material of an adult donor, and so it could be used to create tissue compatible with that of the patient in need of a transplant. This would avoid the problems of tissue rejection and the need for immunosuppressive drugs, as is the case with solid organ donation treatment today. However, to date, no human SCNT lines have been derived, and it is unclear if the technique can be successfully adapted for human biology. More recently, induced pluripotent stem cells have somewhat displaced SCNT approaches, as they appear to offer similar possibilities for the creation of patient-specific tissues using adult somatic cells rather than embryonic cells (Yu et al., 2007).

These developments provoked an energetic social response, as various constituencies, jurisdictions, and religious, civil, and scientific groups mobilized to try and shape the social ordering of the new field. Since the late 1990s, the areas of stem cell science and cloning have attracted extended debate, both in the public domain and in the social science and humanities literature and disciplines, regarding the status of the embryo, the reproductive rights and obligations of women, the entitlements of patient groups and aging populations, the place of State interests, and the commercialization of reproductive biology. In what follows I will give a broad overview of these debates, and the ways different social scientific disciplines have responded to the challenge of analyzing science–society relationships in this area.

Bioethics, Biopolitics, and the Uses of Embryonic Life

The advent of hESC technology and mammalian cloning reanimated a history of public debate and regulatory activity that had its origins in the IVF debates of the early 1980s. At that time, the advent of a new suite of reproductive technologies, including new techniques for handling and researching human embryos as well as distributing gametes, produced a flurry of inquiries and regulatory activity around the world. A suite of complex legislation ensued in many countries after a protracted period of public debate; for example, the Human Fertilisation and Embryology Act (1990) in the UK, and the Embryo Protection Act (1990) in Germany, which set out regulations for embryo research and handling, clinic licensing systems, and the management of gametes. The exception was the USA, where the federal government was silent on social regulation, in part because of a *laissez-faire* attitude toward privately funded research, and in part because of political anxieties over the bitter abortion politics that fiercely polarized American society after the 1973 *Roe v. Wade* Supreme Court decision. Hence the USA did not settle on a coherent regulatory system for embryo research (Jasanoff, 2005).

After the announcement of hESC technology and mammalian cloning in 1997–98, the trajectory of public debate was shaped considerably by this earlier history, although these new techniques also introduced novel quandaries and provocations. They reanimated concerns about the civil and religious status of embryos (Holland et al., 2001), along similar lines to earlier abortion and IVF debates, about the relationship between human origins and human dignity (Habermas, 2003), about the uses and abuses of cloning, with its many dystopian associations (Franklin, 2007), and about the general instrumentalization of reproduction, particularly as it related to the rights of women (Dodds, 2004).

These concerns, while grave, were more inflammatory in some contexts than others. Hence in the USA, with an absence of regulation and a history of polarization around the status of the unborn, the political power of the anti-abortion, anti-stem cell research religious groups was rapidly evidenced by a cascade of bills introduced into the legislature to ban human reproductive cloning and to prevent federal funding for stem cell research. At the same time, supporters of hESC research, including patient groups, research scientists, and the biotechnology industry, mobilized to argue for the importance of medical research, the therapeutic promise of stem cell research, and the status of the United States as a leader in science (Gottweis et al., 2009). While the Clinton administration initially supported a liberal approach, and the National Bioethics Advisory Commission advocated a federal regulatory panel to facilitate research (Jasanoff, 2005), the G.W. Bush, Republican Party administration, after being elected in 2000 gave far more ground to the religious conservatives, and instituted a policy that restricted federal funding to research only on hESC lines already derived at the time of the policy announcement, August 2001. This compromise was sufficiently workable to both appear to be protecting future embryonic life and to allow privately funded research to continue unhindered, while publicly funded research could be carried out in more restricted ways.

In Germany, the advent of Dolly and hESC research also provoked powerful social responses, for reasons somewhat different from the USA. Here the reception of stem cell research was conditioned by the history of eugenics and Nazi medical experimentation, and by a unique set of statutes designed to prevent the recurrence of such a history. The *Grundgesetz*, the German Constitution, makes the protection of the human right to dignity and life the highest duty of the State, and this protection is extended to human embryos through the 1990 *Embryo Protection Act*. This Act falls within the criminal law, and prohibits, among other things, embryo research, germ line manipulation, reproductive and therapeutic human cloning, and hybridization. It prescribes that all eggs fertilized through an IVF procedure must be transferred to the woman from whom the eggs had been taken and the number of embryos transferred is limited to three. No fertilized egg may be stored or destroyed. Its effect is to prevent the generation of surplus embryos through IVF, and to ensure that all embryos created are treated as potential life.

The existence of the *Embryo Protection Act* meant that there was no pressure initially for a government response to the stem cell announcements of the late 1990s. However, the adequacy of this arrangement was thrown into question by an attempt by German medical researchers, supported by the German Research Association, to import embryonic stem cells from Israel. They argued that

> German patients and German scientists should not be excluded from scientific progress. The embryo's right to life should be balanced against the scientists' freedom to conduct research, which is also, argued the association, a high-ranking constitutional guarantee. As long as there was a ban on embryo research in Germany, the association continued, the cell lines should be imported.
>
> (Braun, 2005: 47)

This request unleashed a complex, protracted debate within the Bundestag, regarding Germany's special mission to uphold human dignity, the ambit of the *Embryo Protection Act* and the extent to which it should be applied to non-German embryos, and the appropriate forms of compromise between scientific progress and public morality (Jasanoff, 2005). Eventually, the Stem Cell Law (*Stammzellgesetz*) was introduced in 2002, which permits the importation of existing hESC lines if they meet specific requirements, a decision justified with reference to the fact that cell lines were not embryos, and that the destruction of the embryo had already taken place and was not reversible (Sperling, 2004; Jasanoff, 2005).

Space constraints prevent the canvassing of other national debates. However, numerous policy-oriented studies have been carried out into national, regional, and transnational ethical debates about hESC research, including in Israel (Prainsack, 2006), India (Bharadwaj and Glasner, 2009), the UK (Mulkay, 1997), Australia (Harvey, 2008), South Korea (Gottweis and Kim, 2009), the European Union (Gottweis et al., 2009), Singapore (Lysaght and Capps, 2012), China (Salter, 2009a; Sleeboom-Faulkner and Hwang, 2012), and Jasanoff's (2005) comparative study of Germany, the UK, and the USA.

The State and Regulation

It is evident from the discussion above that provincial, national, and regional administrations have been heavily involved in modulating the public response to hESC research and cloning. While this was also true for the earlier public debates around Assisted Reproductive Technologies, the post-1990s state involvement in stem cell debates and regulation has taken place in a significantly different *economic context*. Two factors in particular have shaped this context. First is the aging of the population in the developed nations, and the search for policy options that can address the growing proportion made up of the retired as compared with the working. Aging populations place large burdens on welfare, care, and pension provisions, at a time when governments in developed nations are working through the fiscal contraction precipitated by the global financial crisis of 2007–08. In this context, medical innovation is highly desirable, as it offers the possibility that currently intractable medical conditions associated with aging and the reduction of employment capacity might be newly treatable, rendering the aging body less dependent and able to remain longer in the workforce (Neilson, 2012). This prospect is particularly appealing in the case of stem cell research, precisely because of its promise to *regenerate* adult tissues, and reverse some aspects of the aging process itself (Cooper, 2006). As Sperling (2004) argues in his study of the German debates around the importation of hESC lines described above, those in favor of importation articulate the need to regenerate the German population as a whole through medical progress.

The second factor is the increasing centrality of the knowledge sector in the national economies of both the developed and the emerging nations. The commercial exploitation of basic science underpins the OECD nations' transition from industrial mass-manufacture economies to knowledge economies, dependent on extensive cooperation among university, industrial and government sectors to pursue promising research directions and strategic advantages. Since the late 1990s, the life sciences have assumed an ever-more prominent place in this model of economic development, a strategy thematized by the OECD notion of the *Bioeconomy* (OECD, 2006). While North America and Western Europe have been the major research economies historically, the advent of embryonic and other kinds of stem cell research has also coincided with the changing geopolitics of life science research, particularly with East Asian and South Asian embrace of innovation-driven development (Salter, 2009b). India and China, as well as South Korea, Taiwan, and Singapore, have invested heavily in biomedical research capacity since the late 1990s, and each of these countries now has a vigorous stem cell research sector (Sleeboom-Faulkner and Patra, 2011; Lysaght and Capps, 2012). Hence stem cell research has become an element in international economic competitiveness.

For these reasons, since the early 2000s many governments have sought to support stem cell research through the development of sector-specific innovation funding and infrastructure building (Harvey, 2012). In the UK, for example, these initiatives have included the creation of the UK Stem Cell Bank and Stem Cell Network, and the allocation of ring-fenced funding through the various Research Councils. In 2007 the Singapore government allocated $8 billion (US) to 2010 for life sciences, including stem cell science, and has made massive investments in research infrastructure since the early 2000s with the creation of the Biopolis life sciences research park (Waldby, 2009). In the USA, in the face of Federal funding restrictions, individual states have undertaken the task of supporting and coordinating innovation, notably with California Proposition 71, which established a $3 billion program in stem cell science by raising state bonds to fund the California Institute for Regenerative Medicine (Adelson and Weinberg, 2010). It is notable that, in some cases at least, research funding has been extended to the social sciences, in recognition of the social complexity of stem cell research. This has been particularly true of the UK, through the ESRC Social Science Stem Cell Initiative, and through project work carried out under the auspices of the ESRC Genomics Network (2002–13).

At the same time, as mentioned above, some states have initiated deliberative processes in order to adjudicate various social views and formulate workable regulations. One notable response has been the creation, with varying degrees of success, of peak bioethics councils or cognate bodies to formulate robust regulations. So, for example, in the USA, President Clinton's relatively liberal National Bioethics Advisory Commission was displaced in 2002 by the Bush Administration's President's Council on Bioethics, with a more conservative membership to appease the right to life constituencies in the Republican Party and the polity at large. Its first action was to advocate a ban on human 'cloning-to-produce children' and a moratorium on human 'cloning-for-research'. In Germany in 2001, Chancellor Schroder formed the National *Ethikrat* to advise him on hESC research in a very hostile social climate. The *Ethikrat* however never developed social acceptance, because it was perceived as too aligned with ruling party interests (Gottweis et al., 2009). In Singapore, a Bioethics Advisory Committee was formed in 2001 to formulate regulations for hESC research, and it has successfully established

itself as a legitimate forum for ethical reasoning and social deliberation on a number of other areas of biomedical research (Reubi, 2010).

The importance of these peak forums is demonstrated in the breach by the Hwang scandal in South Korea. The Hwang case attracted an extensive body of analysis and commentary from science and technology studies scholars, in particular Hong (2008), Kim (2008), Leem and Park (2008), and Gottweis and Kim (2009), as they try to come to grips with different aspects of the case. In terms of regulatory governance, the Hwang case demonstrates the legitimacy problems created both for science and public administration when medical research is poorly regulated. Professor Hwang Woo Suk and his team published two fraudulent papers in *Science* (in 2004 and 2005) falsely claiming to have created the world's first human SCNT cell lines. The fraud was eventually exposed, with dramatic consequences not only for Professor Hwang but also for the government. In subsequent analysis, it became evident that the research fraud was partly the result of granting exceptional status to Hwang's laboratory, and the removal of all obstacles from his research, including oversight. Hence while the Ministry of Science formed a national Bioethics Advisory Committee in 2001, in response to stem cell controversy, its recommendations went largely ignored by government. It was later chaired by Hwang's lawyer Yang Sam-sung. Hwang's SCNT research was later granted an exemption from statutory regulation by the 2005 *Bioethics and Biosafety Act*. The distribution of grants for stem cell research was not based on peer review, but was rather a government decision, and the South Korean government was intent on promoting Hwang as a national hero, so his laboratory received extensive support without scientific oversight. As a consequence, the exposure of the fraudulent research nearly brought down the government. Both the Minister for Science and the head of the BAC resigned.

Feminist Critiques

The Hwang scandal also galvanized and brought wider attention to the feminist critiques of stem cell research. This was the case because Hwang and his team, in their attempt to create human SCNT cell lines, had procured 2221 eggs from 121 women, most from brokers that normally sold Korean oöcytes to Japanese fertility tourists. The rest were donated, including from two research assistants from Hwang's own laboratory team (Leem and Park, 2008). When the research fraud scandal broke, the world's media were also alerted to an ethical issue that had gone relatively unremarked in the early 2000s debates about the status of embryonic life. That is, the dependence of SCNT and many other kinds of stem cell research (embryonic, hematopoietic, and fetal) on women's reproductive biology and the often-onerous nature of the medical processes that precede donation. This dependence has motivated a range of feminist scholarship since the early 2000s. This includes in particular a body of ethnographic and interview-based research that has engaged with the presumptions of regulation to test out the effects of particular policy settings in the clinic itself. So, for example, in most countries that permit and regulate hESC research, embryonic tissue is obtained through the solicitation of what are termed 'spare' embryos – produced as part of *in vitro* reproductive procedures but designated as being surplus to reproductive requirements (Gottweis et al., 2009). However, clinical studies and interviews with both IVF patients and clinicians have demonstrated that the designation of an embryo as 'spare' is not particularly straightforward, either for the donors or medical staff, and that the consent procedures around this process often fall short in recognizing this complexity (Scott et al., 2012). Studies have probed the ways women and couples understand their embryos, including what it means to either bank or discard them (Nisker et al., 2010), and the differences between donating for other couples' reproductive needs, for reproductive medical research and stem cell research (Waldby and Carroll, 2012). It is notable that, despite the fact that almost all of the initial controversy around embryonic stem cell science revolved around the special status of the embryo as an entity with a potential biographical life, a finding of most studies is that women prefer to donate to research where the embryo will be disaggregated, rather than to feel continuing responsibility for what they regard as a genetic child and sibling of their own children; one that has been effectively 'adopted' by unknown parents. A body of feminist research has also been generated around other kinds of stem cell research, notably egg donation for SCNT (Dickenson, 2005; Leem and Park, 2008; Baylis, 2009; Haimes et al., 2012), and the donation of terminated fetuses (Kent, 2012; Pfeffer, 2008) for the derivation of various kinds of stem cells. This latter body of research is concerned to demonstrate the ethical and political complexities of these forms of tissue procurement, despite the absence of embryos.

Translational Medicine, Experimentation, and Medical Tourism

The changing nature and geography of stem cell research since the early 2000s has produced a body of recent social scientific research addressed to a different set of issues. This section will address two very significant developments: attempts to develop stem cell therapies, as opposed to simply carrying out laboratory research, and the growth of stem cell tourism.

The term 'translational medicine' came into wide use in the 2000s to describe the attempts to develop actual clinical therapies from laboratory innovations in stem cell research, genomics, proteomics, and other areas of life science experimentation. This model of clinical development has formed the basis for considerable public funding in some jurisdictions (Harvey, 2012). For this reason, it has also attracted critical social science attention, particularly from scholars working in the sociology of expectations, concerned with how particular ways of imagining the future, including the future of innovation, shape understandings of the present. Along these lines, Wainwright and colleagues interviewed stem cell scientists to identify the nonlinear complexities involved in the purportedly linear process involved in translating research from bench to bedside (Wainwright et al., 2006). Meanwhile, Martin and colleagues approached the issue from a historical perspective, investigating the experimental relations between bench and bedside in the history of bone marrow transplantation using hematopoietic stem cells to treat blood disorders (Martin et al., 2008). They demonstrate that the first experimental bone

marrow transplants (BMTs) during the 1960s and 1970s followed a model of clinical innovation, initiated by clinical hematologists to treat patients without other treatment options. These early attempts had catastrophic results, before laboratory research identified the immunological causes of graft vs host disease and developed methods of precise tissue matching. These laboratory findings provoked a second round of much more successful BMT, recently redefined as hematopoietic stem cell therapy, which is now the standard treatment for many blood disorders. It is notable that, in studies that investigate actual clinical trial and hospital practice around stem cell therapies, this model of hospital innovation and clinical tinkering to find workable treatments for very ill patients can also be identified (Raval et al., 2008), and it is thought that the hospital-based approach is likely to dominate stem cell translational medicine for the foreseeable future (Webster et al., 2011). This domination is in part due to the simpler regulatory approvals process involved in batch-by-batch hospital treatments, while formal clinical trials using hESC lines in particular have been caught up with complex compliance and safety issues.

The demand for new therapies among patient groups, and the social expectations built up around stem cell science have also seen the development of a vigorous stem cell 'tourism' sector, as clinics offer generally unproven stem cell-based treatments to patients willing to travel in order to evade clinical regulation constraints in their own countries. This development is consonant with a more general growth of transnational medical tourism, in which patients travel to gain access to treatments that are unavailable or unaffordable in their own locations. It is estimated that around 700 clinics worldwide currently offer stem cell treatments that have not been validated through clinical trial nor formal evidence-based regulatory assessment (Einsiedel and Adamson, 2012). The potential for harm to patients and the use of direct-to-consumer advertising, which relies on anecdotal accounts of therapeutic success rather than validated scientific evidence (Petersen and Seear, 2011), have alarmed regulators and scientific organizations like the International Society for Stem Cell Research, who have produced patient handbooks and voluntary guidelines for clinics in an attempt to introduce a degree of self-regulation (Harvey, 2012). However, the small amount of fieldwork carried out among stem cell tourists suggests that many make highly informed decisions to access unproven treatments, with complex knowledge of the risks and benefits that may be involved (Song, 2010; Petersen and Munsie, 2012).

Stereotypes in Social Psychology

This article is a revision of the previous edition article by M.R. Banaji, volume 22, pp. 15100–15104, © 2001, Elsevier Ltd.

Abstract

Social stereotypes fulfill a variety of functions and influence social judgment via both automatic and controlled cognitive processes. The formation of shared stereotypes reflects a group's attempt to appraise the social position of relevant out-groups in line with its preexisting norms and beliefs. Competence and warmth organize the content of stereotypes. The position of an out-group on these two dimensions is a function of its perceived status and level of cooperation toward the in-group. When they are shared within majority groups, stereotypes can exert a variety of undesirable influences on the members of minority group.

What Are Stereotypes?

A stereotype is an individual's set of beliefs about the characteristics or attributes of a group (Judd and Park, 1993). Such attributes can typically consist in general psychological traits. A stereotype can also include behaviors considered typical of the members of this social category. Other possible aspects of the stereotype include information regarding the typical norms of this social category or its social status. A stereotype needs not to be disparaging: It can include desirable traits. Stereotypes, being beliefs, should be clearly distinguished from prejudice, which refers to a negative evaluation of a target group. Naturally, of course, stereotypes and prejudice often go hand in hand. Negative stereotypes can foster or justify prejudice.

According to some theorists (e.g., Oakes et al., 1994), a trait can be considered as stereotypical of a given group only if it is perceived as more likely to be present in this group than in other relevant comparison groups. Thus, stereotypes are eminently context dependent. Often, the reference group will be one's own group, in such a way that stereotypes of out-groups are mirror images of one's own (Oakes et al., 1994).

Another definitional question concerns sharedness. Most stereotypes are known by many members of a social group. Hence, they can inform a group's behavior and policies in a much more powerful way than the unique beliefs of a single individual could. This makes it all the more difficult for the members of the target group to escape their influence. The shared character of stereotypes has led Devine (1989) to distinguish cultural stereotypes from personal beliefs. The former refers to stereotypes known to be held in the community but that one does not necessary endorse. The latter concerns beliefs that are subjectively endorsed.

Stereotypes are inherently associated with social categorization, the cognitive process by which individuals are sorted into various social categories. Categorization is a flexible process that depends both on characteristics of the perceived stimuli (in this case individuals) and of the perceiver. People can categorize others in two groups because members of these two groups blatantly differ in their appearance or behavior. In this case categorization is driven by observed regularities as a function of the relevant categorization dimension or *comparative fit* (Oakes et al., 1994). Consider now a situation in which a teacher expects girls to be stronger in literature and boys better in maths (a common stereotype). He may use the gender category to organize his perceptions of the students *even if performance differences between the two genders do not correspond to these expectations*. Here, what determines categorization is 'normative fit' (Oakes et al., 1994). Thus stereotype emerge as much from categorization (comparative fit) as they determine it (normative fit).

It is common to consider stereotypes as an inventory of unrelated traits. Yet, stereotypes often function as 'naive theories' the content of which is dependent on the nature of the associative links between the traits. For example, two individuals may endorse the view that members of a group are 'poor' or 'lazy'. However, they may differ in the theories explaining this association. One may view 'laziness' as causing 'unemployment' whereas another may consider this trait as stemming from discouragement at not being able to find work due to pervasive discrimination. Thus stereotypes not only describe members of a social group but explain *why* they are *how* they are.

Stereotypes often invoke the existence of deep underlying properties that may account for the homogeneity of the group through a form of perception known as *psychological essentialism* (Yzerbyt et al., 1997). Essentialism can be biological when it involves considering that the group's traits stem from shared biological (e.g., genetic) properties. It can also be cultural, when a culture is viewed as determining deep psychological orientations of its members.

The stereotype, as a cognitive structure, should be distinguished from the process of *stereotyping*. Stereotypes involve applying knowledge included in this cognitive structure to specific individuals.

Mental Representation of Stereotypes

Stereotypes have been initially conceptualized as lists of traits describing the relevant category. This representation is then used to appraise new information regarding members of the target group (Katz and Braly, 1933). Critics of this view (e.g., Brewer et al., 1981) have argued that it did not consider variations in the *typicality* of group members. The stereotype is

not applied in an 'all-or-none' manner as the classical view would argue. Rather, the probability that a person belongs to a given category depends on the degree to which it matches the 'typical' member of the category, the 'prototype'.

Both the 'classical' and the 'prototypical' view consider that stereotypes are generalizations based on a large number of observations. A contrasting view (Smith and Zarate, 1992) argues that people hold information about group members in the form of 'exemplars' i.e., individual members of whom they have formed an impression rather than in the form of general abstract knowledge. When judging a member of a social group, or this group as a whole, they rely on the relevant members of this social category that are cognitively accessible rather than on general traits ascribed to the entire group. In this view, stereotypes do not exist as abstract knowledge structures but are just judgments based on whatever exemplars have come to mind.

This approach allows to take into account an important aspect of people's representations of social groups: Even if people strongly adhere to a stereotype, they still acknowledge that group members may vary in their conformity to this stereotype, or even sometimes strongly deviate from it.

In an attempt to reconcile these diverging views, Sherman (1996) has suggested that we need not necessarily choose between an 'abstract' and a 'concrete' model of stereotypes. Indeed, when people form stereotypes of unfamiliar groups, they initially rely on the few exemplars they know. Increasingly, as they become more familiar with the group, they develop more abstract, schematic, representations.

Assessment of Stereotypes

Historically, stereotypes have been assessed through self-report methods, that is, by asking people to explicitly report their beliefs about social groups. For example, the 'checklist approach' pioneered by Katz and Braly (1933) involved asking participants to select five traits descriptive of the target group in a list of 84. Another self-report approach involves asking respondents to estimate the extent to which a group can be characterized by a given trait on rating scales. Thanks to statistical techniques, it is possible to inspect the correlations between the ratings on the individual traits and, in turn, to extract 'dimensions' assumed to organize the stereotype (cf *infra*: the content of stereotypes).

Stereotypes can be conceptualized as representations of the distribution of a set of traits in a group. If this is the case, assessment of stereotypes should provide information on several aspects of these distributions. One such aspect is called its central tendency: What is the 'middle' of the distribution? For example, what level of warmth is expected of the average Italian? Central tendency has received the greatest attention in stereotyping research. Another more neglected aspect of a distribution however relates to dispersion. To what extent are members of the target group perceived to be similar on the given trait, to 'cluster' around the central tendency? People can perceive a trait as very prevalent and yet consider that there is a wide variation in the extent to which members of the target group display this trait. Judd and Park (1993) have developed rating scales assessing the perceived dispersion of a trait in a group.

In spite of their widespread use, rating scales suffer from an important limitation. In general, they do not allow to explore the richness of the explanatory structures underlying stereotypes. Often only the use of more open ended, qualitative methods, does more justice to this richness.

Social norms proscribe the expression and the endorsement of stereotypes about certain groups. If this is the case, self-report measures may be inappropriate as people may hide their true beliefs toward the target group. To circumvent this problem, new measures of stereotypes have been developed by relying on computerized techniques. Typically, these techniques assess *associations* between the social category and a given set of traits. A popular method, the 'Implicit Association Test' (Greenwald et al., 1998), assesses people's associations between the target category and a given trait or set of traits based on reaction times. Unfortunately, such methods remain sensitive to social desirability concerns (although less so than self-report methods). As we should expect, they are not always consistent with explicit ratings and the relation between implicit and explicit ratings is on average quite low although it can increase under specific conditions.

Functions of Stereotypes

Tajfel (1981) distinguishes the *individual* and *social functions* of stereotypes. At an individual level, stereotype first serve a function of cognitive economy: Indeed, stored knowledge about an individual's group may be readily applied to interpret his or her behavior, or even to evaluate this person, without having to engage in in-depth impression formation. This function is particularly meaningful when cognitive resources are taxed or when facing a large number of individuals.

Stereotypes may also help guide behavior. By relying on stored information regarding the members of a social group, one can more easily behave in appropriate ways toward members of this group.

At a collective level, stereotypes are used by groups to explain societal events. This function is particularly salient in conspiracy theories depicting members of a social group as the organizers of a plot leading to an unfortunate event.

One step further, stereotypes can be used to *justify* the existing social structure and/or the discriminatory behaviors displayed by members of the dominant groups. By attributing 'essential' traits to members of a stigmatized group, they may conceal the role of power dynamics and oppression, portraying the group's position as the outcome of its inner characteristics (cf Jost et al., 2004). For example, gender inequality may be attributed to women's natural inclinations toward child rearing and family life.

Finally, according to Tajfel, stereotype may be used to differentiate the in-group from relevant out-groups. Thus, by portraying the in-group in a favorable light, compared to the out-group, stereotypes may promote or maintain a 'positive social identity'. This may explain why self-stereotypes (i.e., stereotypes of the in-group) are generally more positive than heterostereotypes (i.e., stereotypes of the out-group).

In view of these functions, stereotypes appear like interpretational devices that help individuals and group appraise and understand others' behaviors. Stereotyping does not

necessarily imply imposing an a priori view of someone on his or her behavior. Much more subtly, it may help fill the gaps in our understanding of others when we lack all the information necessary to make a judgment.

Since Tajfel's seminal work, other functions of stereotypes have been uncovered.

At the individual level, stereotypes may help individuals cope with the fear of death. Indeed, according to terror management theory, people hold 'cultural worldviews', i.e., a set of beliefs about the organization of the world and about important values shared within a culture (Schimel et al., 1999). According to this theory, the primary function of these worldviews, of which cultural stereotypes are part, is to protect people against the fear of their own mortality.

A collective function that has attracted increasing attention is collective mobilization. Stereotypes are very efficient rhetorical devices, which can be used to mobilize other group members into supporting the speaker's political projects (Klein et al., 2007). As stereotypes are collectively understandings of the important groups composing one's social environment, they provide a readily accessible 'image' of the social structure on which group leaders can capitalize to mobilize support for their political projects.

Stereotype Content

The content of stereotypes is generally organized around two broad dimensions (Fiske et al., 2002): One pertains to the group's skills and capacities (the competence dimension); another to his or her intentions toward the self or one's in-group (the warmth dimension). As a consequence, it is possible to classify groups in four quadrants depending on their position on these two dimensions. Such an analysis reveals that most out-groups are perceived ambivalently as high on one dimension and low on the other. Thus, envied groups (e.g., Jews and Asians in the US) are high on competence, and low on warmth. By contrast, other groups, victims of paternalistic prejudice (e.g., housewives and disabled people in the US) are low on competence and high on warmth (cf **Table 1**).

Table 1 Four types of out-groups, combinations of status and competition, and corresponding forms of prejudice as a function of perceived warmth and competence

	Competence	
Warmth	*Low*	*High*
High	Paternalistic prejudice Low status, not competitive Pity, sympathy (e.g., elderly people, disabled people, housewives)	Admiration High status, not competitive Pride, admiration (e.g., in-group, close allies)
Low	Contemptuous prejudice Low status, competitive Contempt, disgust, anger, resentment (e.g., welfare recipients, poor people)	Envious prejudice High status, competitive Envy, jealousy (e.g., Asians, Jews, rich people, feminists)

Reproduced from Fiske, Susan T., Cuddy, Amy J.C., Glick, Peter, Xu, Jun, 2002. A model of (often mixed) stereotype content: competence and warmth respectively follow from perceived status and competition. Journal of Personality and Social Psychology 82, 878–902.

Importantly, the position of a group on these two dimensions can be predicted by sociostructural variables. Perceived warmth is a function of perceived cooperation (vs competition) between the in-group and the out-group whereas the competence dimension is a function of perceived status.

This is consistent with the suggestions that stereotypes not only serve to describe the out-group but to explain, and even justify, this group's relative position within the social structure vis-à-vis the in-group.

Recent research on these two dimensions of social judgment suggests that they may be negatively related. Thus when a group is perceived as high on one dimension, it may tend to be perceived as low on the other. A similar pattern holds when making intergroup comparisons: when compared to a more competent group, a group is also perceived as warmer.

A specific form of group perception that has attracted attention recently concerns the perceived *humanity* of groups (Haslam and Loughnan, 2014). Historically, foreign, or unknown, groups have often be portrayed in animal terms (e.g., Rwandan Tutsis as 'cockroaches' by the Hutu propaganda during the genocide). An indicator of humanization, as opposed to animalization, is the attribution of emotions. Some emotions, called 'secondary emotions' are typically human (e.g., nostalgia, guilt,…) whereas others (e.g., fear, joy), called 'primary emotions', are common to both humans and animals. People tend to routinely 'infrahumanize' out-groups by attributing them fewer secondary emotions than their in-group. Such a form of group perception seems particularly likely when the out-group is potentially threatening to the in-group.

Stereotype Accuracy

Whereas stereotypes have often been characterized as 'inaccurate' or 'exaggerated', current definitions do not consider inaccuracy as a property of stereotypes.

Researchers trying to estimate the accuracy of stereotypes have found that, on average, they tended to be relatively accurate at predicting the central tendency of the relevant traits in the target group (Jussim, 2012). If stereotypes are sometimes good at predicting group level tendencies, they are generally of little use in predicting an individual's characteristics. This is because social category membership explains very little variance on most psychological traits.

Nevertheless, comparing stereotypes with 'reality' poses methodological and conceptual difficulties.

First, given that stereotypes help explain relations between social groups, it should come as no surprise that they may also change as a function of the evolution of these relations (e.g., Poppe, 2001). An individual's stereotype may also vary depending on the situation in which the target group is evaluated, and of the group to which it is compared (Oakes et al., 1994). Thus, the stereotype to be gauged in terms of accuracy is often an elusive target.

Second, the norm against which stereotypes are compared, 'reality', can change very quickly as well. For example, in a study by Guimond et al. (2006), differences between the

self-concepts of men and women were a function of the context in which participants were asked to describe themselves. Gender differences, with men being more 'independent' and less 'interdependent' than women, were most likely to emerge when group members compared themselves to members of the other gender (i.e., because it activated their gender identity).

Third, when assessing stereotype accuracy, it is important to distinguish the accuracy of the description from the accuracy of the explanation. Establishing a correlation between a social category and a stereotypical trait does not demonstrate that the social category plays a direct role in the existence of this covariation (i.e., correlation does not imply causation). Thus, finding that a stereotype is 'accurate' does not tell us anything as to why there is a correlation between the category and the trait.

Fourth, a reason why stereotypes can be accurate is that they can produce the reality they describe even when they are initially inaccurate (i.e., 'self-fulfilling prophecy'). Thus, when large segments of a powerful group hold a stereotype of another, less powerful group, they may influence members of the latter into adopting social roles and positions that call for the qualities that are part of the stereotype (Klein and Snyder, 2003).

Development and Diffusion of Stereotypes

Children acquire stereotypes as early as four. It is tempting to view children's minds as a 'blank slate' on which adults' views are progressively imprinted. Reality is more nuanced. According to developmental intergroup theory (Bigler and Liben, 2007), stereotypes develop in three stages.

First, children identify person dimensions (e.g., sex, gender, occupation) as relevant. This may occur because a given dimension is highly visible or discriminable. It may also be because it is used by peers and adults to characterize others.

Second, children use these dimensions to characterize others.

Finally, they develop stereotypes. The content of these stereotypes depends on four different factors:

- Essentialism or the tendency to attribute essences (cf supra) to social groups.
- In-group bias refers to a motivation to describe one's group in a favorable light compared to other groups even in the absence of evidence. Thus, children may literally invent stereotypes to depict their group in a positive light.
- Stereotypes can be shaped by adults' or peers' explicit remarks about the characteristics of social groups.
- Finally, children develop stereotypes based on the observation of correlations between social categories and attributes. For example, children may notice that most teachers are female or that most politicians are male.

Thus, the development of social stereotypes is not simple brainwashing. Neither should it be understood as a pure inductive process based on the solitary observation of the social world. Children elaborate stereotypes to the extent that these offer them as satisfactory understanding of the world. They depend on the frame of references provided by their group's norms and beliefs. Peers and parents provide them cognitive tools that may help them appraise the humans that surround them. For this reason, children's, like adults', stereotypes are malleable and highly dependent on the social context in which the target group is judged (Oakes et al., 1994).

Generally, stereotypes are not maintained if they are not shared and communicated within the group, a process known as consensualization. As people communicate about others, they tend to preferentially select information that conforms to existing stereotypes, thereby contributing to their diffusion and maintenance (cf Kashima et al., 2007). By being communicated within the group, via interpersonal communication or the media, stereotypes are socially validated and become shared understandings that are incorporated in the group's view of the organization of the social world, i.e., its ideology.

Stages Involved in Stereotyping

How do stereotypes affect the impression human form of other persons? In their influential *continuum model*, Fiske et al. (1999) suggest that, when encountering another person (the 'target'), one may engage in two types of processing. At one extreme, one can attend to the person's appearance and behavior and derive an individualized impression of this person. At the other extreme, one can categorize a person in a social group and perceive this person in terms of the stereotype associated with this social category regardless of his or her observable attributes. The latter type of processing is less demanding than the former in terms of cognitive resources. As a consequence, it will often tend to be preferred especially when attentional resources are scarce, when the perceiver is under time pressure or when there are limited opportunities for more effortful deliberate processing.

The continuum model (Fiske et al., 1999) considers impression formation as involving sequential stages: People initially try to categorize the person in terms of the activated stereotype, process information relevant to this stereotype only. If they do not succeed, they recategorize the person in terms of a new stereotype and consider information relevant to this new category. They attend to individuating information that does not fit into any accessible stereotype only when all attempts at categorization fails. In contrast to such a *serial model*, Kunda and Thagard (1996) have suggested that people often process category based and individuating information *in parallel*. In this view, all the information about a target is activated concurrently and may influence the impression simultaneously.

To impact on judgment of others and behavior, stereotypes first need to be made accessible for further treatment, a process known as *activation*. An important question concerns whether such an activation is automatic or controlled: After having categorized a person in a given group, can observers refrain from activating the associated stereotype? A process is considered automatic, as opposed to controlled, if it is unintentional, efficient (i.e., requires few cognitive resources), occurs outside awareness and is uncontrollable once triggered. Stereotype activation satisfies many of these criteria. When people are confronted with cues associated with a person's social category, stereotype consistent information becomes more easily accessible. This occurs even when these cues are presented subliminally or cannot be consciously processed (Devine, 1989).

This means that stereotype activation often occurs without control, awareness of intention.

However, stereotype activation remains susceptible to controlled processes (Blair, 2002). The activation of stereotypes can be influenced by the perceiver's goals. In certain cases, the regulation of stereotypes may become controllable. Also, activation seems to require some cognitive resources. Hence, it is best characterized as 'conditionally' automatic.

In addition, members of a cultural group do not necessarily activate the same stereotype when confronted with a social category. People low in prejudice, or those chronically motivated by egalitarian norms, may activate more positive stereotypes than others. They may also be more capable of regulating the impact of stereotypes on their judgment of others. This form of control may become so habitual in 'egalitarians' that it occurs swiftly and without awareness (Moskowitz, 2010). Such findings blur the boundary between 'automatic' and 'controlled' processes.

Once stereotypes are activated they may influence several stages of impression formation: Thus, they may lead observers to focus on dimensions of the target's personality that are associated with the stereotype and fail to notice aspects of the target's personality that are not represented in the stereotype. They may also lead observers to interpret ambiguous behavior in line with their stereotypical expectations. The activation of stereotype seems to trigger associations that thoughtlessly influence the interpretation of ambiguous behavior (cf Devine, 1989).

Finally, under certain conditions, the activation of stereotypes by a 'prime' may induce people to unknowingly behave in line with the traits that are part of the stereotype. For example, in a classic study, people walked more slowly after the concept of old age was activated (Bargh et al., 1996). Due to a common representational basis, the activation of the trait may lead to the production of the behavior. Whether such effects are truly automatic has been a matter of controversy (cf Doyen et al., 2012).

Stereotype activation should be distinguished from stereotype application: People can inhibit the application of a previously activated stereotype, for example because this stereotype does not conform to social norms. However, such inhibition attempts could backfire (Macrae et al., 1994) by making it more accessible. As a consequence, inhibition may subsequently increase the chances that it will color judgment of others once the perceiver does no longer try to suppress it, a pattern known as a 'rebound' effect.

Stereotype application may also be encouraged in response to specific motivations. For example, people have been found to apply stereotype when their social identity, self-esteem, or core aspects of their cultural worldview were threatened.

Stereotype Change

Changing an individual's beliefs regarding a target group is rarely a simple matter. Intergroup contact (Allport, 1954/1979) is a much-studied strategy for modifying stereotypes and decreasing prejudice. This intervention is presumed on the assumption that negative stereotypes may be due to insufficient knowledge of the out-group. Under certain conditions, developing environments allowing intergroup contact has indeed been shown to decrease prejudice and stereotyping (Pettigrew and Tropp, 2008). However, many hurdles have to be cleared in order for exposure to counterstereotypical group members to undermine stereotypes (Klein and Snyder, 2003). First, counterstereotypical behaviors need to be noticed and interpreted as such. If this is the case, people may still characterize such behavior as driven by situational factors rather than by the persons' dispositions. Even when observers attribute such behavior to the target's dispositions, they may still 'fence off the target' and characterize her as an atypical exemplar of her social category, a process known as 'subtyping'. Thus, for stereotype change to take place, the target needs to be perceived as typical of the group in spite of her stereotype inconsistent behavior. Finally, although a single deviant group member may sometimes affect perceived group variability ('they are not all alike'), observers may need to be exposed to many instances of stereotype disconfirming behaviors, from different members of the target group, to expect an alteration in this group's perceived 'central tendancy' on the given trait.

Thus the journey to stereotype change through the cognitive pathway is a rocky one. If contact may lead to a change in stereotypes and prejudice, it may be primarily by influencing the observer's affective ties with the out-group (e.g., by making friends in the out-group) rather than via cognitive processes exclusively (Pettigrew and Tropp, 2008).

Since stereotypes are inherently associated with the social position of the in-group and out-group, the best hope for change is the evolution of these relations. It is only insofar as stereotypes successfully explain the organization of the social structure in which groups are placed that they can persist.

Influence of Stereotypes on the Target Group

Members of groups targeted by social stereotypes are affected by these in many ways. Some of these consequences are relatively direct, such as discrimination. Indeed, stereotypes can prompt or justify discrimination (Allport, 1954/1979).

However, they are more subtle consequences of negative stereotypes. An important such consequence has to do with the difficulty of identifying whether other people's negative behaviors toward the self are due to the stereotype or, worse, to prejudice than to other factors. Attributing such behavior to prejudice may protect self-esteem (Crocker et al., 1991). For most people, performance feedback may also be used to correctly assess one's capacities. When one belongs to a stigmatized group, suspecting that this feedback is biased by stereotypes may promote a sense of uncertainty about one's capacities.

When stereotypes depict the abilities of members of a group in a negative way, stigmatized group members may be tempted to psychologically withdraw ('disengage') from this domain. If they are nevertheless confronted with the stereotype, they may also adopt compensatory strategies to help maintain their self-esteem in case of failure, such as devoting less effort to the task in an attempt to 'explain away' a possible failure.

People who keep identifying with a domain in which their group is viewed negatively may succumb to another hazard known as 'stereotype threat'. In a pioneering study, Steele and Aronson (1995) have found that the activation of the African-

American stereotype lead members of the stereotyped group to perform more poorly in a stereotype relevant task (an intelligence test) than if they had not been reminded of the stereotype. Similar findings have been reported for other target groups and stereotypes (Schmader et al., 2008). This phenomenon depends on the situational salience of a stereotype and does not specifically target chronically stigmatized groups.

Stereotype threat effects on cognitive performance occur in domains that demand a high level of mental concentration. The activation of the stereotype seems to mobilize much needed cognitive resources. And indeed, impaired working memory capacity has been shown to explain womens' tendency to underperform in maths when the stereotype is salient (Schmader et al., 2008).

To combat the stigma associated with negative stereotypes, members of the stigmatized group may engage in two types of strategies (Klein and Snyder, 2003).

One type of strategy is individual and involves dissociating the self from the negative stereotypes to achieve positive relations with members of the nonstigmatized group. Thus, the stigmatized compensatory behaviors, such as behaving more assertively or devoting more effort to establish smooth interpersonal relationships. Reacting to the stereotype is of course much easier when it is blatantly endorsed or expressed by members of the nonstigmatized group. More often than not, however, the stereotype is conveyed subtly or implicitly and it can be difficult for members of the target group to notice it and therefore to react effectively.

Rather than dissociating themselves from their stigmatized group, people may adopt a 'collective strategy' and choose to confront the image held by the dominant group about their in-group, or 'metastereotypes'. Faced with negative metastereotypes, group members may collectively strive at changing it in an effort to upgrade their image (Klein et al., 2007). However, in other circumstances, stigmatized group members actively conform to negative metastereotypes in order to distance themselves from the dominant group (Kamans et al., 2009).

Whether people resort to the 'individual' or 'collective' strategies seem to depend once again on the nature of the relations between the groups and especially on several factors: first, whether the boundaries between the in-group and the out-group are permeable (i.e., whether it is possible to 'pass' from one group to the other). Second, whether the status differences between their stigmatized in-group and the nonstigmatized group is perceived as legitimate (which may be especially the case, when the stigma, such as obesity for example, is perceived as controllable) and stable. According to social identity theory (Tajfel and Turner, 1986), the use of collective strategies aimed at upgrading a stigmatized social identity is most likely when group boundaries are perceived as impermeable, and status differences are perceived as either unstable and/or illegitimate. These predictions have generally been supported although little research has considered how these applied to stereotypes per se (Klein and Snyder, 2003).

Abstract

S. Smith Stevens (1906–73) was a leading figure in the field of experimental psychology during the middle part of the twentieth century. He is best known for his work in psychophysics and especially for the development of the psychophysical power law, an empirical description of the relation between the intensity of stimuli such as sound and light and the perceptual magnitude experienced by an observer. He was also a pioneer in the study of hearing and did important work on the theory of measurement. Aside from his many research reports, his most influential publications include the classic *Hearing: Its Psychology and Physiology* (1938), coauthored with Hallowell Davis, the *Handbook of Experimental Psychology* (1951), and *Psychophysics: Introduction to Its Perceptual, Neural and Social Prospects* (1975), edited by his wife Geraldine Stevens.

Beginnings

To understand fully the significance of any scientist's contribution, it is important to know the context in which it occurred. It is particularly useful to be acquainted both with the scientists who paved the way and with those who followed. Historians of experimental psychology have traced the beginnings of the field to the German scientist Wilhelm Wundt (1832–1920), who established the first laboratory for psychological research in 1879. Although other scientists had made important contributions to the emerging field, it was Wundt who first identified an entire range of questions in psychology amenable to laboratory investigation, and it was to his laboratory in Leipzig that students from many countries came for training in experimental psychology. Stevens, whose distinguished career culminated in his position as Professor of Psychophysics at Harvard University, stands in a direct line of scholarly descent from Wundt as a member of the fourth generation. He was trained by E.G. Boring (1886–1968) at Harvard, who in turn had studied at Cornell with E.B. Titchener (1867–1927), an Englishman who had received his degree in Leipzig from Wundt in 1892. And whereas Wundt may be considered the first to devote himself to Experimental Psychology, it may well be that Stevens was the last. His work marked and contributed to a transition from one era to another in the evolution of scientific psychology; an understanding of that transition makes an interesting story.

Stevens was born on 4 November 1906 in Ogden, Utah, home to the Mormon Church. Following the customs of that institution, he departed at the age of 17 to spend 3 years as a missionary in Belgium and later in France, despite a complete ignorance of French. It seems likely that this experience contributed to the development of persistence and determination, traits that were to serve him well in his career as a scientist. On his return he entered the University of Utah and, after 2 years, transferred to Stanford, where he graduated in 1931 having taken such a wide variety of courses that the identification of a major was problematic. He was accepted by the Harvard Medical School but demurred on the grounds that the required payment of a $50 fee and the need to spend the summer taking a course in organic chemistry seemed equally unattractive. But he did decide to study at Harvard, and duly enrolled in the School of Education as the easiest (and most economical) path to Harvard's resources. The transforming experiences there were E.G. Boring's course on perception and service as Boring's unpaid research assistant. By the end of his second year, Stevens had earned a PhD in the Department of Philosophy (from which the Psychology Department emerged a year later). A year studying physiology under Hallowell Davis and another as a research fellow in physics led to appointment in 1936 as an instructor in the Psychology Department, where he remained until his death on 18 January 1973. By 1946 he achieved the rank of full professor, and in 1962 the University acceded to his request that he be named Professor of Psychophysics in honor of the field founded a century earlier by G.T. Fechner, whose theories, ironically, Stevens worked hard to refute.

Stevens's Psychophysical Power Law

Scholars familiar with his work quickly could agree in making a list of Stevens's major achievements, but could and do disagree about their relative importance and their lasting value. For some, the single most important accomplishment was his discovery of the psychophysical power law that sometimes does and always should carry his name (Stevens, 1957). He not only revived a view broached by some in the nineteenth century, but also created a body of evidence that firmly established what is sometimes called the psychophysical power law and sometimes Stevens's Law. It concerns the relation between the strength of some form of energy, such as the sound pressure level of a tone, and the magnitude of the corresponding sensory experience, loudness in this example. It is easily discovered that sensation strength is nonlinearly related to stimulus intensity (two candles do not make a room seem twice as bright as one), but it is harder to say what that relation is. For over a century before Stevens approached the problem, the prevailing view, Fechner's Law, asserted that as stimulus strength grew geometrically (by constant ratios), sensation strength increased arithmetically. This logarithmic relation had little supporting evidence but remained in many texts for lack of a good alternative. Stevens came to a different conclusion on the basis of data obtained by asking observers

who were presented with stimuli varying in intensity to make numerical judgments of their subjective experience. In the case of loudness he found that judged loudness grew as a power function of sound pressure (with an exponent of about 0.6), but not as the logarithmic relation predicted by Fechner (Stevens, 1961). A similar relation was found to hold between judged brightness and luminance, and eventually, such a relation was found for dozens of other continua. In each case, as the amount or intensity of a stimulus grew by ratio steps, so too did the observer's estimate of his subjective experience of it. Stevens's Law seemed applicable to all intensive perceptual continua.

Equally interesting was the discovery that for each perceptual continuum, there was a distinctive value of the exponent relating numerical judgment to stimulus intensity. In hearing, for example, a huge range of sound pressures was compressed into a much smaller range of loudness, whereas for electric shock applied to the fingertips, a quite small range of currents between detectability and pain was expanded into a larger range of perceived intensities.

Although Stevens originally argued that the method of magnitude estimation provided a 'direct measure' of sensation and that the power law described how energy in the environment was transformed through the relevant sensory apparatus into sensation, critics soon showed this assumption to be untenable. What remained was an empirical principle relating judgment to stimulus intensity.

Stevens went on to show that numerical magnitude estimation was a special case of a more general paradigm, cross-modal matching. If the observer is asked to match loudness, for example, by manipulating the luminance of a light source until its brightness matches the level of the target loudness, the power relation is again the result. And, neatly enough, the exponent of that function is exactly predictable by the exponents identified through magnitude estimation of brightness and loudness alone (Stevens, 1969). It is this ability of observers to match perceived magnitudes across many different perceptual attributes, and the discovery that in all cases the result is described by a power function that are the two pillars on which Stevens's Law rests. Despite the many controversies over its meaning, this simple empirical principle stands securely on a mountain of evidence and must be accommodated by any theory of psychophysics. And indeed, it has been incorporated into a more general model that, starting with the premise that a power law describes the relation between sensory magnitudes and stimulus intensity, adds the idea that the various sensory systems vary in dynamic range and in resolving power, but all map into a single scale of perceived magnitude with its own characteristic dynamic range and its own resolving power (Teghtsoonian, 2012). It remains to be seen whether such a theoretical construct has some observable neural foundation.

Scales of Measurement

Others attach greater importance to Stevens's ideas about scales of measurement. In a seminal paper (1946) he created a taxonomy of measurement, which identified four classes of scales – nominal, ordinal, interval, and ratio – distinguishing among them on the basis of the operations that leave the form of the scale invariant. Nominal scales assigned numbers that serve only to distinguish one event or class of events from another (the classic example is the set of numbers used to identify each member of a team); any one-to-one substitution is permissible because player identity is preserved. Ordinal scales of measurement permit a rank ordering of measured events (relative hardness of materials, for example) and will remain invariant under monotonic increasing transformations. Interval scales entail a constant unit of measurement and so permit the calculation of differences between any two values (as for the common scales of temperature) and remain invariant under linear transformations. Ratio scales (the bread and butter of physics) also feature constant units of measurement, but in addition allow the expression of two values as a ratio, since a true zero exists; weight is a good example. Such a scale is invariant under a simple multiplicative transformation.

It is harder to assess the impact of this conceptualization of measurement than that of the work on cross-modal matching judgments. The latter was instrumental in creating new bodies of knowledge, especially in the field of sensory psychology, and continues to play an influential role in psychophysical theory and research. But Stevens's four-step hierarchy of measurement scales encountered an assortment of reactions that leaves its present status in some doubt.

Contemporary theorists find the nominal scale of little interest because it imposes no ordering on the measured entities. And several authorities have noted the omission of a log interval scale from what Stevens had proposed as an exhaustive listing. The relevance of this classification to the selection of statistical procedures was hotly debated (e.g., see Binder, 1984). Stevens had argued that the type of measurement placed constraints on which statistics can be used, but statisticians were quick to cite seeming exceptions, and the usefulness of Stevens's measurement taxonomy as a guide to the selection of statistical techniques became uncertain.

But, for psychologists, his ideas about measurement were, and in some ways continue to be, of great importance. At a time when Stevens was trying to provide support for his newly-created scale of loudness, he felt it important to show that it met the same criteria of legitimacy as did the familiar scales of the more developed sciences. It was a time when the status of psychology as a science was a topic of lively debate, and Stevens was much involved in efforts to identify the critical features of science and the ways in which psychology shared them. During the 1940s and 1950s, questions about the nature of science and psychology's place in it were discussed at length, and Stevens's analysis of measurement in general and the ways in which psychologists could use scales of measurement was very influential. The idea that a measurement scale – or, for that matter, any lawful relation – could be expressed in terms of the operations that left it invariant played an important role in the thinking of his students, and no doubt for scientists in other disciplines as well. The work that Stevens began has now evolved into a mathematical specialty in its own right, yielding results that confirm some of what Stevens intuited, and disconfirming other aspects of his work. (It must be remembered that the ideas he was advancing lent themselves to

mathematical formalization, though he himself did not provide it.) That his ideas about measurement have continued to be developed and refined by other scientists today may be the ultimate accolade for his pioneering work in this field (e.g., see Luce and Narens, 1999).

Hearing

If Stevens had never established the psychophysical power law and had left the study of measurement untouched, he would still be known and remembered as a pioneer in the field of psychoacoustics, the scientific study of the perception of sound (e.g., see Scharf, 1999). His collaboration with Hallowell Davis in the late 1930s resulted in *Hearing*, a book that for many years was the fundamental source on the subject and has been ranked by some scholars as second only to the work of Helmholtz in its originality and breadth. In addition to his measurements of loudness, he did important work on auditory localization, and on the relation of pitch to intensity. At the behest of the US Army Air Corps he established the Psycho-Acoustic Laboratory at Harvard in 1940 to study the effect of noise on pilot psychomotor efficiency. As its director he was able to attract a group of students and colleagues of extraordinary ability; among them were W.R. Garner, K.D. Kryter, J.C.R. Licklider, and G.A. Miller, all of whom made important contributions to psychoacoustics and beyond. It was an interesting aspect of his personality that, despite a rather gruff manner, he functioned as an intellectual magnet, attracting to his laboratory some of the most talented researchers in the world. Not the least of these was G. von Békésy, who spent almost 20 years in Stevens's basement lab and won a Nobel Prize during that period for his early work (in Budapest and Stockholm) on the ear.

Throughout his career there were several periods of intense activity as a laboratory scientist. But in the period before World War II, he was also active in the discussion of philosophical questions about the nature of psychology. He was impressed by the work of the physicist P.W. Bridgman on the central role of operationism in science, and argued for its use in defining the concepts of psychology. And for a period he was associated closely with a group of logical and methodological positivists whose ideas about the nature of science seemed especially hospitable to a behaviorist psychology (Stevens, 1939). Perhaps, one manifestation of this outlook was a reluctance to extend his thinking very far beyond his data. In a period when many experimental psychologists were developing ever more complex theoretical systems, Stevens's own forays into the realm of theory were few and limited in scope. He seemed happiest examining his data (as well as those of others) to see what useful information could be extracted. Much of his time in the laboratory was spent plotting and replotting data in the pursuit of clarity and simplicity, and his research reports were models of both qualities.

Impact on Experimental Psychology

Two additional characteristics of his work deserve mention. While the majority of his contemporaries were engaged in a search for relevant variables (e.g., does 'meaningfulness' affect ease of remembering?), Stevens's goal was the discovery of functional relations, mathematical descriptions of the association of one factor with another, as epitomized by his psychophysical power law. A corollary of this belief was an attitude toward sampling theory and statistical testing that ranged from indifference to disdain. The object for him was not to see whether 80 dB tones received an average loudness judgment greater than did 60 dB tones (at the 5% level of significance), the equivalent of what most of his contemporaries were doing. What was important to Stevens was whether a lawful relation could be seen when data were plotted in a thoughtful way. Large numbers of experimental subjects were not needed to reveal the kind of robust relations he sought; a few colleagues or students recruited in the hallways were enough for most of his purposes.

A landmark publication for research psychologists in the 1950s was the *Handbook of Experimental Psychology* edited by Stevens (1951). It was, as he described it in the preface, "a technical survey that would systematize, digest, and appraise the mid-century state of experimental psychology." It was not the first of its kind, but it was the most recent, and thus defined for teachers and students alike the set of shared interests that constituted experimental psychology. It was a time still when one might be expert in one aspect of the field and fairly knowledgeable about many others. Since then the amount of knowledge in psychology has grown at an explosive rate, and now the achievement of competence in one area increasingly restricts knowledge of any other. At the beginning of the twenty-first century, the tent of 'experimental psychology' has few remaining occupants; there are instead cognitive scientists, brain researchers, vision scientists, and a host of others in specialized niches. Just as Stevens's mentor E.G. Boring may have been among the last to teach an all-inclusive account of psychology in a single course, so Stevens may have been among the last to view the phrase 'experimental psychology' as a useful rubric.

Conclusion

Stevens can be seen as a transitional figure in the evolution of psychological science, yet much of what he did continues to influence the way it is practiced today. His lasting contributions to the fields of psychoacoustics and psychophysics have been discussed here. But, in addition, he created a roadmap for much of modern sensory neurophysiology and for those who theorize in that area. Many of the phenomena for which today's brain researchers seek explanations were established by Stevens or by others using the methods he developed. Were he alive today, it seems likely that he would embrace the new technology and would be developing ingenious techniques for exploring the neural aspects of sensory events. Although an account of his influence remains an unfinished story, at the least he will be remembered as one who brought new and powerful ideas to the study of psychophysics, leaving it a field reinvigorated and evolving as a subject of great intrinsic interest and many useful applications (e.g., see Baird, 1997; Norwich, 1993; Stevens, 1966).

Abstract

George Stigler, a key member of the 'Chicago School' of economic thought, made major contributions to the history of thought, price theory, economics of information, organization of industry, and the theory of economic regulation. He taught at Iowa State University, the University of Minnesota, Brown University, Columbia University, and the University of Chicago, where he also served as editor of the *Journal of Political Economy*. He was President of the American Economic Association in 1964, and of the History of Economics Society in 1977. He received the Alfred Nobel Memorial Prize in Economic Science in 1982.

Personal History

George Stigler, one of the great economists of all time, with a gift for writing matched among modern economists only by John Maynard Keynes, was born 17 January 1911 in Renton, Washington, a suburb of Seattle, the only child of Joseph and Elisabeth Stigler. His parents had separately migrated to the United States at the end of the nineteenth century, his father from Bavaria, his mother from what was then Austria-Hungary. Stigler went to public schools in Seattle, and then to the University of Washington, receiving a BA in 1931. Although he says that he had 'no thought of an academic career' when he graduated from college, he applied for and was awarded a fellowship at Northwestern University for graduate study in the business school, receiving an MBA in 1932 (Stigler, 1988, p.15). More important, at Northwestern he developed an interest in economics as an object of study in its own right and decided on an academic career. After one further year of graduate study at the University of Washington, he moved to the University of Chicago where he found the intense intellectual atmosphere he sought. Chicago became his intellectual home for the rest of his life, as a student from 1933 to 1936, a faculty member from 1958 to his death in 1991, and a leading member of, and contributor to, the 'Chicago School' throughout. He received his PhD in 1938, with a thesis, now a classic, on the history of neoclassical theories of production and distribution (Stigler, 1941).

At Chicago, Stigler was particularly influenced by Frank H. Knight, under whom he wrote his dissertation, Jacob Viner, who taught economic theory and international economics, John U. Nef, economic historian, and their younger colleague, Henry Simons, who became a close personal friend and whose *A Positive Program for Laissez Faire* greatly influenced many of Stigler's contemporaries.

'At least as important to me,' Stigler writes (1988, pp. 23–5), 'as the faculty were the remarkable students I met at Chicago,' and goes on to list W. Allen Wallis, Milton Friedman, Kenneth Boulding, and Robert Shone from Britain, Sune Carlson from Sweden, Paul Samuelson, and Albert G. Hart – all of whom subsequently had distinguished careers.

In 1936, Stigler was appointed an assistant professor at Iowa State College (now University), and shortly thereafter was married to Margaret Mack. The Stiglers had three sons: Stephen, a professor of statistics at the University of Chicago, David, a lawyer in private practice, and Joseph, a businessman. Mrs. Stigler died in 1970, tragically without any advance warning. George never remarried.

In 1938, Stigler accepted an appointment at the University of Minnesota, going on leave in 1942 to work first at the National Bureau of Economic Research and then at the Statistical Research Group of Columbia University, where he joined a group directed by W. Allen Wallis that was engaged in war research on behalf of the armed services. When the war ended in 1945, George returned to the University of Minnesota, but remained only one year, leaving in 1946 to accept a professorship at Brown University, where he also remained only one year before moving to Columbia University in 1947 and then, in 1958, to the University of Chicago where he remained the rest of his life. At Chicago, he became an editor of the *Journal of Political Economy*, established the Industrial Organization Workshop, which achieved recognition as the key testing ground for contributions to the field of industrial organization, and in 1977 founded the Center for the Study of Economy and the State, serving as its director until his death in Chicago on December 1, 1991.

Stigler served as President of the American Economic Association in 1964, and of the History of Economics Society in 1977. He was elected to the National Academy of Sciences in 1975. He received the Alfred Nobel Memorial Prize in Economic Science in 1982 and the National Medal of Science in 1987.

Stigler's governmental activities included: serving as a member of the Attorney General's National Committee to Study the Antitrust Laws, 1954–5; Chairman, Federal Price Statistics Review Committee, 1960–1; member, Blue Ribbon Panel of the Department of Defense, 1969–70; Vice Chairman, Securities Investor Protection Corporation, 1970–3; Co-Chairman, Blue Ribbon Telecommunications Task Force, Illinois Commerce Commission. 1990–1.

Scientific Contributions

Stigler made important contributions to a wide range of economic areas: (a) history of thought, (b) price theory, (c) economics of information, (d) organization of industry, and (e) theory of economic regulation. In addition, (f) he wrote many influential essays and reviews, and was a long-time editor.

Intellectual History

Intellectual history was Stigler's first field of specialization and remained a continuing interest throughout his life. His doctoral dissertation, published as *Production and Distribution Theories*, was followed by a steady flow of perceptive, thoughtful, and beautifully written articles and books interpreting the contributions of his predecessors. Almost single-handedly, he kept the field alive, despite widespread lack of interest within the profession. More recently, he succeeded in bringing about a revival of interest in the field, which is currently flourishing. In the words of one of his students, 'The versatility of his work in [the history of economic thought] has been matched by its depth and insight – and unmatched by any other historian of economic thought' (Sowell 1987, p. 498; the rest of this paragraph draws from Sowell's excellent summary of 'Stigler as an Historian of Economic Thought'). In addition to analyzing the theories of particular economists, he examined particular concepts, such as perfect competition and utility, traced trends in the economics profession, considered the influence of economic theories on events and vice-versa, and the meaning of originality. Many of his important articles in this area are collected in a 1965 volume, *Essays in the History of Economics*.

The history of thought provided a rich seedbed for Stigler's wide-ranging scientific work. Stigler regarded economic theory, in the words of Alfred Marshall, as 'an engine for the discovery of concrete truth,' not as a subject of interest in its own right, a branch of mathematics. Few economists have so consistently and successfully combined economic theory with empirical analysis, or ranged so widely.

Price Theory

Stigler's first important publication after his doctoral thesis was a textbook, *The Theory of Competitive Price*, published in 1942, followed by four revised versions under the title *The Theory of Price* (1946, 1952, 1966, 1987). His textbook is unique among intermediate textbooks in price theory in its systematic linking of highly abstract theory to observable phenomena. It is unique also in its concise yet rigorous exposition.

One of his earliest papers (1939) broadened the concept of a short-run cost curve to accommodate the observation that firms faced with fluctuating demand could build flexibility into their fixed equipment at a cost of not achieving the lowest possible cost for a particular output.

Another early paper (1945) presented a formal analysis of determining the minimum cost of an adequate diet, supplemented by an empirical calculation of the minimum cost – one of the earliest applications of linear programming. 'The procedure,' he explained, 'is experimental because there does not appear to be any direct method of finding the minimum of a linear function subject to linear conditions' (p. 310). Two years later George Dantzig provided such a direct method, the simplex method, now widely used in many economic and industrial applications (1987).

Like these two examples, Stigler's many later contributions to price theory were a by-product of seeking to understand puzzling real world phenomena, and are best discussed in that context.

Economics of Information

'The Economics of Information' is the title of a seminal article, published in 1961. In his intellectual autobiography, Stigler termed it, 'My most important contribution to economic theory' (1988, pp. 79–80). The article begins, 'one should hardly have to tell academicians that information is a valuable resource: knowledge is power. And yet it occupies a slum dwelling in the town of economics. Mostly it is ignored' (Stigler, 1961, p. 213).

This brief 12-page article is a splendid illustration of several of Stigler's unique virtues: creativity, which he defined as consisting 'of looking at familiar things or ideas in a new way'; the capacity to extract new insights about those seemingly familiar things; and the ability to state his main points in a provocative and eminently readable way.

Stigler illustrates the importance of subjecting information to economic analysis with two familiar observations—that there is generally no single 'market price' but a variety of prices that 'various sellers (or buyers) quote at any time' and that 'advertising ... is an enormously powerful instrument for the elimination of ignorance ... and is normally "paid" for by the seller.' In each case, he presents a sophisticated analysis that explains what determines the observed phenomena, an analysis that has empirical implications capable of being contradicted by observation. He concludes that 'The identification of sellers and the discovery of their prices are only one sample of the vast role of the search for information in economic life' (quotes from Stigler, 1988, pp. 213, 220, 221, 224).

As occurred throughout his career in every field Stigler touched, this article was less important for the particular familiar observations that it analyzed than for giving birth to an essentially new area of study for economists. There followed an outpouring of further studies by him but even more by his students and others that have radically altered the accepted body of economic theory.

This aspect of his influence was stressed in the citation for his Nobel Prize, which noted that Stigler's 'studies of the forces which give rise to regulatory legislation have opened up a completely new area of economic research ... Stigler is also recognized as the founder of "economics of information" and "economics of regulation," and one of the pioneers of research in the intersection of economics and law.'

The Organization of Industry

The Organization of Industry is the title of a book published in 1968. Its 'main content,' Stigler says in the preface, 'is a reprinting of 17 articles I have written over the past two decades [including the "Economics of Information"] in the area of industrial organization. Although the main topics in industrial organization are touched upon, the touch is often light. The ratio of hypotheses to reasonably persuasive confirmation is distressingly high in all of economic literature, and it must be my chief and meager defense that I am not the worst sinner in the congregation.' Far from being the worst sinner, Stigler's main contribution to the field, both in this book and later writing, was the use of empirical evidence to test hypotheses designed to explain features of industrial organization. Article after article combines subtle theoretical analysis

with substantial nuggets of empirical evidence, presented so casually as to conceal the care with which the data were compiled and the effort that was expended to determine what data were both relevant and accessible. These articles record the shift in Stigler's views on antitrust – from initial support of an activist antitrust policy to skepticism about even a minimalist policy.

One of the most influential of the articles in the book was on 'The Economies of Scale' in which he introduced 'the survivor principle' as a way to use market data to determine the efficient size of an enterprise in a particular industry. The approach has since become widely accepted.

In 1962, he published an article, in collaboration with Claire Friedland, his long-time associate, entitled 'What Can Regulators Regulate? The Case of Electricity,' which concluded that regulation of electric utilities had produced no significant effect on rates charged. Schmalensee (1987, p. 499) notes that 'This essay stimulated a great deal of important empirical work on public regulation in the USA. It also posed a basic problem: if regulation does not generally achieve its stated objectives, why have so many agencies been established and kept in existence?'

Economic Regulation

'The Theory of Economic Regulation' (1971b) attempts to answer that question. It is one of a series of contributions by Stigler to what has since come to be called 'public choice' economics: the shift from viewing the political market as not susceptible to economic analysis, as one in which disinterested politicians and bureaucrats pursue the 'public interest,' to viewing it as one in which the participants are seeking, as in the economic market, to pursue their own interests, and hence subject to analysis with the usual tools of economics. The seminal work that deserves much of the credit for launching 'public choice,' *The Calculus of Consent*, by James Buchanan and Gordon Tullock (1962), appeared in the same year as the Stigler–Friedland article.

The 'central thesis of the article,' Stigler wrote, 'is that, as a rule, regulation is acquired by the industry and is designed and operated primarily for its benefit.' He notes that two 'alternative views of the regulation of industry are widely held. The first is that regulation is instituted primarily for the protection and benefit of the public at large or some large subdivision of the public. The second view is essentially that the political process defies rational explanation.' He then gives example after example to support his own thesis, which is, by now, the orthodox view in the profession, concluding: 'The idealistic view of public regulation is deeply imbedded in professional economic thought. The fundamental vice of such a [view] is that it misdirects attention' – to preaching to the regulators rather than changing their incentives (quotes from Stigler, 1971b, p. 3).

'Smith's Travels on the Ship of State' (1971a), published in the same year as 'The Theory of Economic Regulation,' raises the same question on a broader scale. Smith gives self-interest pride of place in analyzing the economic market, but does not give it the same role in analyzing the political market. Smith's failure to do so constitutes Stigler's main – indeed, nearly only – criticism of the *Wealth of Nations*, that 'stupendous palace erected upon the granite of self interest' (Rosenberg, 1993, p. 835). The same theme pervades many of Stigler's later publications.

Essays, Editorship, and Reviews

In addition to his prolific academic publications, Stigler published a great many essays for a broader audience, many given as talks to a wide variety of audiences. The most important are collected in three volumes, *The Intellectuals and the Marketplace* (1963), *The Citizen and the State* (1975), and *The Economist as Preacher* (1982). 'There he (the intelligent layman) will find a potpourri of wit and seriousness blended with a high writing style' (Demsetz, 1982, p. 656). 'For 19 years Stigler was a very successful editor of the *Journal of Political Economy*. Under his leadership this journal solidified its high reputation among economists' (Becker, 1993, p. 765).

Stigler was also a prolific reviewer of books. His complete bibliography lists 73 reviews in 24 publications ranging from strictly professional, such as the *Journal of Political Economy* (22) and the *American Economic Review* (10) to the popular, such as the *Wall Street Journal* (5), and the *New York Times* (3), and dating from 1939 to 1989.

Stigler's last book, his intellectual autobiography, published in 1988, *Memoirs of an Unregulated Economist*, is a delight to read. As I described it at the time: 'Stigler's memoirs are a gem: in style, in wit, and above all, in substance, they reflect accurately his own engaging personality and his extraordinarily diverse contributions to our science.'

Concluding Comments

An evaluation of Stigler's scientific contribution would be incomplete without recognizing his role as a teacher and colleague. As teacher, he inspired his students by his own high standards, and instilled a respect for economics as a serious subject concerned with real problems. As one of his students, Thomas Sowell, wrote (1993, p. 788): 'What Stigler really taught, whether the course was industrial organization or the history of economic thought, was intellectual integrity, analytical rigor, respect for evidence – and skepticism toward the fashions and enthusiasms that come and go.'

Stigler supervised many doctoral dissertations at both Columbia and the University of Chicago. According to Claire Friedland, Stigler's associate for many years, he served on more than 40 thesis committees at Chicago, and perhaps 40 more at Columbia, and chaired a considerable fraction of those committees. His students come close to dominating the field of industrial organization.

Stigler was an extremely valuable colleague. He provided much of the energy and drive to the interaction among members of the Chicago economics department, business school, and law school that came to be known as 'The Chicago School.' His Workshop in Industrial Organization was an outgrowth of a law school seminar started by Aaron Director that Stigler cooperated in running when he came to Chicago. His relations were especially close with Aaron Director, Gary Becker, Richard Posner, Harold Demsetz, and myself, enhancing significantly the scientific productivity of all of us.

Abstract

A stigma is an attribute of an individual or a group that compromises full acceptance from others. Those who possess a stigma are stigmatized, referring to the process of derogation and devaluing that may lead to immediate and long-term social, psychological, economic, and health-related injustices that divide human society. Over the last century, research on people with stigma has evolved from controversial origins into a model social science research program, with contributors from diverse social backgrounds and academic disciplines, working on a range of issues related to stigma.

A stigma is an attribute of an individual or a group that compromises full acceptance from others. Those who possess a stigma are stigmatized, referring to the process of derogation and devaluing that may lead to immediate and long-term social, psychological, economic, and health-related injustices that divide human society. Stigmatizing attributes are often esoteric, context dependent, and changing across human eras and cultures, so that the very trait that is highly stigmatizing in one society or era may be deemed irrelevant or even valued in another. The term stigma itself finds unsettling origins in the ancient practice of marking the skin of those who are socially rejected, although in present usage a stigma may be a figurative rather than a literal marking. While stigmatization remains one of the regrettably enduring features of human society, it is matched by an equally long history of stigmatized individuals, groups, and their allies mobilizing in interpersonal and collective resistance against externally imposed disadvantages.

History of Stigma Research

Over the last century, research on people with stigma has evolved from controversial origins into a model social science research program, with contributors from diverse academic disciplines and social backgrounds, working on a range of issues.

Early 'Race Theory'

In the early part of the 1900s, scientists did not have an integrated theory of the psychology of stigma, per se. Instead, an assortment of individual small-scale disaggregated studies were published (in many academic disciplines), usually 'exposing' an unseemly or tragic nature to the lives of a specific marginalized social group (e.g., people with disabilities, African-Americans, or people living in urban poverty), with the aim of documenting deviation, promoting social concern, and discussing intervention. At this time of dramatic intentional social reorganization, science was the newly recognized authority on how to manage and direct social interventions. These new experts on the human social order employed ethically and scientifically dubious research methods. Portrayed as the downfall of contemporary social progress, stigmatized groups were cataloged and classified to include people referred to variously as epileptics, the feeble-minded, the insane, the morally deficient, criminals, drunkards, the poor, the blind, the deaf-mute, the migraneous, neurotics, hysterics, the paralytic, the sexually depraved, unmarried mothers, the syphilitic, the tubercular, wanderers, and runaways. Some of the earliest writers in the scientific community weighing in on stigma would be the Social Darwinists who minimally tolerated the existence of lower social castes of 'defectives' and 'degenerates' as inevitable by-products of human evolution. Fueled with eugenic derision, some published bogus claims about the innate moral inferiority of nonwhite Western peoples around the globe while others turned their attentions locally, deriding low-income 'degenerate families' in their own communities (Guthrie, 2004). Condescension and victim blaming began to grow in the medical community. For example, Baker and Smith (1939) concluded in the *Journal of the American Medical Association* that facial 'disfigurement' was often inextricably linked with defective personality. With a small sample of a mere 12 plastic surgery patients "taken for detailed study," the authors lamented that many who "experienced very creditable surgical results, have remained unsatisfied and have shown that they are sick and maladjusted persons" (p. 301). Similar derision can be found in the field of education, as in a study of 'mental defectives' written by Leta Hollingworth (1920) warning teachers that 'subnormal children' were social menaces:

> At the extremely low end of our curve we have the undesirable and unfortunate deviates, the dull, the subnormal. They constitute a great burden, economically and socially. …By intermarriage with the more intelligent, subnormals tend to degrade all the social body. By marrying or cohabitation among themselves they produce a numerous offspring and increase the financial burden on public and private charity. Psychologists working in penal institutions and courts have shown conclusively that crime and delinquency of all kinds are closed related to mental subnormality. Alcoholism is closely bound up with mental deficiency… Disease easily originates…and is spread broadcast by them. The problem of the unmarried mother is to be understood more clearly in light of mental inferiority. (p. 18)

Sharing the sentiments of her contemporaries, Hollingworth also explains that Black Americans have lower intelligence quotients because any ancestors "caught and led into slavery

were on the average more stupid" and that the relationship between "feeble-mindedness" and poverty is such "that the former is the cause for the latter" (p. 15). Many early scientists endorsed these 'race theories,' proposing that stigmatized groups are separate and inherently defective races of humans. Influential race theorists such as Herbert Spencer, Edward Thorndike, and Francis Galton advocated for social policies to manage inferior races: lower educational standards (for inferior minds), moving people back to farms (to prevent urban slums), no minimum wage and no unions (so that work was only merit based), and no social charity of any kind (to inhibit poor parents from having many children). Initial scientific efforts to address marginalized stigmatized groups encouraged rigid segregation, institutionalization, sterilization, imprisonment, hospitalization, restrictive marriage, deportation, and extermination.

The Social Gospel

Subsequently, a new agenda was championed by minister and activist Washington Gladden, dubbed the 'social gospel,' promoting Protestant Christian sympathies for the 'downtrodden' and offered an alternative to the race theories of the time (Hilgard, 1986). These advocates, including such notable social scientists as Goodwin Watson, Kurt Lewin, and Gynnar Myrdal, favored sociological explanations over notions of willful degeneracy or innate deviance. Thus, the scientific value of essentialist work on stigmatized groups was increasingly contested in the years approaching World War II (WWII), including criticism by the newly formed activist psychological organization Society for the Psychological Study of Social Issues in the late 1930s. Growing in influence were the ideas of anthropologist Franz Boas who introduced 'culture' as an antidote to eugenicists' naturalistic arguments of essential inferiority. Merton (1938) argued that being poor does not induce crime, but instead crime is induced by being poor in a culture that values material wealth while preventing everyone from having equal access to it. The most impactful research during this era involved in the famous 'doll studies' conducted to prove that cultural and psychological damage had been done to the self-concept of African-Americans (Clark and Clark, 1939). Although based on what later scholars found to be exaggerated, misrepresented, and inconsistent findings (Cross, 1991; Jackson, 2001), concerns about African-Americans' shame and self-hatred led the United States to end segregation in the 1954 *Brown v. Board of Education* Supreme Court decision. Despite their virtuous sympathies, these social scientists still favored an elitist scientific 'objectivity' that spoke for stigmatized groups, "fixing" social problems on behalf of stigmatized communities, instead of empowering stigmatized communities to define and address their social problems from within. The social gospel was noticeably patronizing and denigrating in tone by contemporary standards, leaving a legacy of etiological attributions to 'inferior culture' that later social scientists would need to redress. In time, stigmatized group members would redirect the discourse on stigma, rejecting both the race theorist's charge of innate inferiority and the social gospel's charge of deficient culture.
